The variegated sandstones and coloured clays of the British series, being destitute of organic remains, and subject to no very remarkable changes of character, what has been said will suffice for the purpose of comparison between them and the analogous deposits in other parts of Europe. But before we proceed to this comparison, it will be useful to describe more particularly the general characters of the terrace of magnesian limestone, and its associated strata, which occupies so remarkable a range in the North of England. The table already given will explain the relation of the several members of this group, and we shall at present confine our attention to the calcareous portions. The most ample details on every point will be found in Professor Sedgwick's Paper in the *Geological Transactions*.

Marl slates.

Immediately above the lower red sandstone in the excavation for the Stockton Rail-road, were found in ascending order, (1.) thirty feet of light-coloured, silicious sandstone in thin beds, alternating at the top with blue calcareous slate. (2.) Nine feet of yellow calcareous shale and marl slate, some of the beds incoherent and sandy. In this marl slate about two feet above the sandstone were found many impressions of vegetables (ferns) and fishes of the genus palæothrissum. The higher and more compact beds also contained productæ, spiriferæ, and terebratulæ. The shales or marls of this series are sometimes highly bituminous. (3.) Twenty feet of thin calcareous beds with marly partings.

These slaty marls and limestones have a very irregular extent even in Durham, and are imperfectly traceable in Yorkshire. They are perhaps best exhibited at Garforth Cliff, on the road from Leeds to Selby, where they are full of axinus obscurus, and contain a species of producta not yet described. Deposits somewhat analogous are described by Professor Sedgwick near Bolsover. Little or no magnesia is found in this part of the series.

Yellow magnesian limesto

The yellow magnesian limestone whose extreme thickness between the Aire and the Dun certainly exceeds 300 feet, exhibits the most astonishing diversity of mechanical structure, without a corresponding diversity of chemical composition or definite geological divisions. Several varieties yield upon analysis carbonate of magnesia and carbonate of lime, in the simple proportion of atom to atom, (for example, the building stone of Huddleston and Warmsworth,) and in almost all the proportion of magnesia is large. In the Southern part of its range, the structure of the rock is generally crystalline, and the crystals (rhomboids) being small, and often tinged of a reddish or yellow colour, the whole might be easily mistaken for sandstone. On the contrary, in the Northern part of its range, a concretionary structure is often observed, and thus globular masses of carbonate of lime of various magnitude compose beds of stone or lie loose amongst a quantity of yellow, powdery, calcareo-magnesian carbonate. But the variety of the appearances presented by this kind of structure is so great, that on entering a quarry near Sunderland we are struck by the organic aspect of the whole escarpment, as if it had been a reef of coral. On the coast of Durham beds of this structure appear associated with masses of brecciated limestone, but very irregularly, and under circumstances not easily explained, without supposing the deposits to have been subject to repeated local and violent disturbance.

Certain beds of this rock in Yorkshire and Derbyshire are very compact; in Durham some are composed of numerous thin, incoherent layers. In several places North of the Dun and near Tadcaster oolitic portions are distinguishable.

But by far the most plentiful of all the varieties of this changeable rock, especially to the North of the river Wharfe, is a loose earthy mass of indistinct beds, with hollow geodes of crystallized carbonate of lime, and numerous veins or strings of the same substance, dividing the rock into angular cells, and helping to hold it together. This character of crystallized cavities and sparry strings is very common to the whole formation, and we occasionally find oxydulated iron, sulphate of strontian, or sulphate of barytes in these cavities. In the quarries at Weldon occur layers of silicious nodules, analogous to the chert lumps in limestone, in oolite, and green sand, and to the flints in chalk. Veins of sulphate of barytes cross the magnesian limestone in several places near Ferrybridge, and near Wetherby. Galena occurs in it at Mansfield and at Warmsworth near Doncaster in small veins, and in other places in detached crystals, as does also sulphuret of zinc; carbonate of copper lines some joints of the rock at Newton Kyme near Tadcaster, at Warmsworth, and at Farnham near Knaresborough; muriate of soda has been obtained by Mr. Holmes from the red beds of Mansfield, and a solitary lump of red rock salt was found in connection with it near Pontefract.

Organic remains of retepora, crinoidea, brachiopodous bivalves, and other shells of mollusca, occur in this rock, in by far the greatest abundance near Sunderland in Durham; they are much less plentiful in the upper parts of the rock in Yorkshire between the Dun and the Wharfe; and only a few species obscurely show themselves in Derbyshire and Nottinghamshire. There is a great analogy between the organic remains in the magnesian limestone of Durham, and those of the older carboniferous limestone, and it especially deserves attention that in this rock the genus producta is seen for the last time as we ascend the series of strata, while no ammonite has yet been found in it.

Above the yellow magnesian limestone is a series of gypseous red and white marls, fifty feet thick or more, and this is surmounted by the upper laminated limestone.

Upper laminated limestone.

This rock is not coextensive with the yellow limestone, but has a more limited range, scarcely extending beyond the boundaries of Yorkshire. It is most fully developed in the tract between Tadcaster and Tickhill, and may be examined advantageously at Brotherton and Knottingley, where enormous quantities of it are burned annually to lime for agricultural purposes.

It here reaches to about fifteen yards in thickness, and is composed of a vast number of small irregular layers, separated more or less by partings of marl, and obscurely united into uneven and often undulated beds. The stone is nearly devoid of magnesia, its substance is usually compact, so as even to fit it imperfectly for the purpose of lithography; it is remarkably full of dry cracks, which have dendritical faces, and small cavities lined with crystallized carbonate of lime appear in the thicker layers. The thickness of the layers increases suddenly, or the beds become more consolidated toward the bottom, and in this part the crystallized cavities become more numerous and larger, the stone is less compact, holds more magnesia, and is of no value for lime. The prevalent colour of the stone is a smoke-grey, which is often disposed in spots or stripes, and the separating marls are generally light grey, but often purplish, and further South reddish.

Organic remains occur but very rarely, and in the lower beds only. They are very imperfect in general, but appear to be of the same species as others from the yellow limestones of the same vicinity.

Further North, at Nosterfield, these beds change their aspect considerably, so as to resemble closely some kinds of carboniferous limestone, a resemblance increased by the presence of productæ, and the occurrence of galena. About Doncaster this rock assumes a redder aspect, and contains some beds full of magnesia. It is then said to be a *hot lime*, and like the product of the yellow limestone, is injurious if laid on the land in large quantity.

The stony beds mentioned in the general classification of the saliferous system occur at a few points about Gainsborough in Lincolnshire, and Tuxford in Nottinghamshire, as we learn from Mr. Smith, who distinguishes it by the provincial title of *waterstone;* and perhaps the hard white beds at Newnham in Gloucestershire may be referred to the same rock. Its course remains to be further traced, and deserves attention as perhaps affording a term of comparison with the magnesian layers described by M. Elie de Beaumont in the variegated marls of Alsace.

Rock salt.

The following abstract of Mr. Holland's Paper in the *Geological Transactions*, vol. i., will convey a good notion of the situation and mode of deposition of the rock salt in Cheshire.

Character of the country.

Cheshire unites with the Southern part of Lancashire and the Northern part of Shropshire into a great plain, fifty miles long from North to South, and about twenty-five or thirty wide. It is bounded on the East and on the West, and interruptedly on the South, by carboniferous ranges of hills; and the internal area is divided by two ranges of rising ground into three minor plains, which serve to conduct the Dee, the Weaver, and the Mersey to the Irish Channel. The range of Delamere Forest on the West, and an undulated tract ranging nearly Westward to Halton and Runcorn, define the drainage of the Weaver, and include the most abundant sources of salt. Scarcely any rock salt is found except in this limited tract. On approaching the estuary of the Mersey, the ridges which bound the plain approach one another at two points, and suggest the idea of the included plain having been once a lake.

The salt which lies under this plain is found to thicken, at least partially, toward the contraction of the valley; it does not, however, lie beneath the whole surface of the low ground, nor indeed in one connected mass, but occurs in detached masses of limited area. The rock salt of Northwich ranges North-East and South-West, and its breadth is about three-quarters of a mile. The upper bed is thickest on the North-West, and thins off toward the South-East.

Two beds of salt at Northwich, &c.	
Rock salt..	20 to 30 yards.
Parting of marls, &c.	11 yards.
Rock salt	35 yards known.

Three beds at Lawton.	
42	yards marl, &c.
4	feet salt.
10	yards marl, &c.
12	feet salt.
15	yards marl, &c.
24	yards salt.

The upper bed has been worked through only at Northwich and Lawton. No marine exuviæ occur over the salt, or in any way associated with it. The purest part of the salt in the upper bed is about three or four yards above the bottom of the bed, and about four feet in thickness; the purest part of the lower bed is twenty or twenty-five yards deep in it, and five or six yards thick, below which the salt becomes earthy as above. This is the part worked. The salt is not stratified, but divided into vertical prisms of various polyhedral forms, and different magnitudes, sometimes a yard or more in diameter. The sides of these prisms consist of pure white salt. Gypsum abounds in the marls associated with the salt, the most abundant variety being the fibrous kind.

Mr. Holland supposes that what is now the salt field was once a salt-water lake, separated from the sea by a natural dam; that the evaporation of the water caused the precipitation of the salt, and that it was afterwards covered with the laminated marls. To account for so much salt, he imagines that the sea might often overpass the dam.

Perhaps we may say that there was here a lake of salt water, of which the deposit went on gradually, and that at intervals violent floods filling it with muddy matter, this was precipitated with gypsum, but without salt, but that afterwards the water again subsiding, salt fell as before. If the floods came in from the sea, this might explain the correspondence in character of these gypseous marls, and those which elsewhere belong to the Keuper era.

Section. Northwich.

English Geologists have, till lately, commonly believed that rock salt was the peculiar production of the red marl and red sandstone; but the mines of Wielitzka are in green sand, those in the Salzburg Alps in limestone of the oolitic period.

By far the larger proportion of ordinary springs, from whatever strata they issue, yield muriate of soda, sometimes in very large quantity, and it is important to know that bromine and iodine, which are stated to be always existent in the actual sea water, very generally accompany the muriatic salts in common springs. This is most remarkably the case with bromine. (See *Phil. Trans.* 1830.) The rock salt of Cheshire is perhaps entirely devoid of bromine and iodine, though the brine springs of the same district are found to contain both. The reason of this may be that the hydrobromic and hydriodic salts have not the same ratio of solubility as the muriate of soda.

Saliferous System of Europe.

General view.

We are now at liberty to consider the characters of the saliferous system as they appear in the other parts of Europe, which have been accurately examined by Geologists. This comparison is much facilitated by the mutual understanding now so general between English and foreign observers, and the subject is made familiar to our countrymen by the published inferences of Sedgwick, Voltz, and De Beaumont. The Rhine in its Northward course from Basle divides into two unequal parts an immense area, in which the saliferous system mantles round the primary ranges of the Vosges, Schwartzwald, Odenwald, Spessart, Thuringerwald, and Harz mountains. The natural boundaries of this irregular area, are, on the West, South, and South-East, the French, Swiss, Swabian, and Bavarian ranges of Jura limestone; on the North-West, the slate formation of the Ardennes, Nassau, and Westphalia; on the North the tertiary plains of Northern Germany. Over all this immense tract, the saliferous system contains a calcareous stratum at present unknown in Britain, called the Muschelkalk, a rock which, in some of its external characters, particularly its smoke-grey colour, and association with marls, bears a considerable analogy to the upper layers of the magnesian limestone formation of England, but by the occasional abundance and general character of its organic remains is strongly assimilated to our lias.

Organic remains.

In several districts different portions of the sandstones and marls contain organic remains both animal and vegetable, which are entirely distinct from those yet known to belong to the older formations, but greatly resembling those of the lias and oolites, so that the foreign localities of the new red sandstone series supply us with those links in the chain of general Geological facts which are wanting in Britain, and for want of which English Geologists have been accustomed to view in too absolute a light the distinction between the carboniferous and the oolitic formations. On the other hand, in the greater part of the saliferous system on either side of the Rhine, beds corresponding to the magnesian limestone of England are entirely unknown. It is chiefly along the line of the South-Western face of the Thuringerwald, prolonged to the North-West as far as Münden, in the drainage of the Weser, along the Southern and Eastern borders of the Harz, and on the North-West side of the slate formation connected with the Erzgebirge, in the drainage of the Elster, that the zechstein and rauchwacke represent on a greater scale the yellow magnesian and upper laminated limestone of the North of England.

Salt which, as above explained, occurs in England in beds only in the variegated marls, is found in one or other side of the Rhine in every bed of the system.

From these remarks it is evident that there is a great general resemblance between the characters of the saliferous formation as it exists in Germany, France, and England; but to make the differences equally apparent, it will only be necessary to fix our attention upon two districts in particular, *viz.*, the Vosges mountains, which range to the North-East parallel to the Rhine, and the district in the North-East of Upper Germany, adjoining the Thuringerwald and the Harz mountains.

The general succession of strata in the saliferous system round the Vosges mountains may be well seen on the road from Metz to Strasburgh; and the minuter details of the beds have been ascertained by those eminent Geologists, Voltz and Elie de Beaumont; to the former of whom we owe the discovery of most of the vegetable fossils of these rocks, and to the latter a valuable discussion of the relations of the formations.

Between the bottom of the oolitic system and the top of the saliferous system occurs, about Luxemburg especially, a peculiar sandstone, which has hardly been distinctly recognised in any other situation. Below this, in descending order, is the following series of strata.

Section of the Vosges.

4. Variegated marls, Keuper of Germany, marnes irisées of France.—Red, pale blue, greenish, &c., with gypsum occasionally interstratified, especially near the top, with beds of sandstone of different kinds, containing plants of the families calamites, equisetaceæ, lycopodiaceæ, coniferæ, cycadeæ, &c., univalve and bivalve shells, remains of saurians and chelonida.

In these coloured marls, above the middle, lies a regular bed (six to ten feet thick) of extremely compact magnesian, yellow limestone, without fossils, and under it, in several places, black schistose marls; in this part, also, gypsum is especially abundant. In several situations, thin bands of reddish limestone occur, alternating with anhydrite.

3. Muschelkalk.—Limestone, generally compact, of a light grey or smoky colour, with partings of marl, containing peculiar encrinites, with ammonites, plagiostomata, and other shells analogous to those of the oolitic system, and remains of reptiles. Near Luxemburg it is very thin, and may easily be mistaken for lias; near Saverne it is much thicker, and more characteristic. At Bourbonne les Bains it is a true magnesian limestone. As before observed, it does not exist in England.

2. Variegated red sandstone. (*Bunter sandstein* of Germany, *grès bigarré* of France)—Extremely similar to the new red sandstone of England. This also contains, locally, abundance of organic remains, both animal and vegetable.

1. The strata above named rest, in some places unconformably, upon a vast thickness of red sandstone, in general much coarser, and more like a conglomerate than the variegated red sandstone; the pebbles of quartz, which it contains in abundance, appearing to be derived from the ruins of portions of the primary rocks of the range of the Vosges. The magnificent precipices down which the road descends to Saverne, among grand old woods and torrents, are formed by this rock, and the resemblance which it bears to the old red sandstone conglomerate of Monmouthshire, is such as to bias the English Geologist strongly in favour of that approximation. In other cases, and especially in hand specimens, this rock appears to resemble the coarse red sandstone of Dumfries-shire and of Penrith Beacon, and as these rocks certainly overlie the carboniferous series, this comparison may, perhaps, be exact. The Northern part of the Vosges mountains being wholly composed of these grit rocks, and coal beds being found at many points in the same vicinity, the incumbency of the red sandstone upon the coal is satisfactorily proved.

The lower part of this thick arenaceous group, which rests upon the coal series, is usually of a friable and fragmentary nature, containing admixtures of porphyritic masses, which strongly assimilate it to the red sandstone conglomerate of Exeter, and the red sandstone, expressively so called, of the North of Germany. The upper part, also, gradually becomes finer grained, and more like the ordinary variegated red sandstone; but as in several places this latter rock rests unconformably upon the other, we are justified in adopting the opinion of Voltz and De Beaumont, that it is a portion of the red sandstone series, almost peculiar to the Vosges mountains, and may, therefore, be characterised as the *grès des Vosges.*

North-East of Germany.

The North-East of Germany gives us the following section of the saliferous system.

5. Variegated marls (*Keuper, marnes irisées*) with gypsum, and the usual characters of the strata.

4. The muschelkalk, much as it occurs about the Vosges. It admits of subdivision into two, or, perhaps, three parts, which, according to Hoffman, may be distinguished by their respective types of organic remains.

3. Variegated sandstone. (*Bunter sandstein, grès bigarré.*)

2. Zechstein, or magnesian limestone formation, consisting of the following members:—

a. Rauchwacke, asche, stinkstein, &c. with gypsum.
Coloured marls.
b. Kupferschiefer and zechstein.

1. Lower red sandstone, (*Rothetodteliegende, grès rouge,*) which is often associated with porphyritic masses like the red sandstone of Exeter.

The following Table will show the relations of the three tracts.

England.	France.	Germany.
4. Variegated marls.	5. Marnes irisées.	5 Keuper.
	4. Muschelkalk.	4. Muschelkalk.
3. Variegated sandstone.	3. Grès bigarré.	3. Bunter sandstein.
2. Magnesian limestone.	....	2. Zechstein.
1. Lower red sandstone.	2. Grès des Vosges. 1. Grès rouge.	1. Rothetodteliegende.

A more minute analysis of the zechstein and magnesian limestone series furnishes the following comparison.

England.	Germany.
Upper laminated limestone.	Stinkstein, Rauchwacke, &c.
Gypseous coloured marls.	Coloured marls and gypsum.
Yellow magnesian limestone.	Zechstein.
Marl, slate, and fishes, or limestone with shells.	Kupferschiefer, and fishes of Mansfeld.
Lower red sandstone.	Rothetodteliegende. (Upper part.)

Coal formation.

And we might by a diagram express the gradual change from one of these types to another, putting the Vosges section between those of England and Germany.

With respect to organic remains it may be sufficient to remark generally that they are found locally in abundance in all the members of the saliferous series in Germany and France, while hitherto they have appeared in England confined to the two lowermost groups.

Salt.

It appears that the greater part of the salt beds of Germany occur in the muschelkalk, between Magdeburg and Osnabruck, and in the Valley of the Neckar in Würtemberg. At Vic, Baden, and Lons le Saulnier, salt lies in red marl, along the North side of the Tyrolean alps in red sandstone, (Altenau, Berchtolgaden,) and it is possible that the abundant salt-works on both sides of the Carpathians in Transylvania and Moldavia may be established on this series. The salt of European Russia (Strangways, in *Geol. Trans.*) is also connected with the new red sandstone; but the geological age of the salt amongst the sands (said to be red) of Persia, in India between the Indus and Chellum, in Africa, New Holland, and North America, is at present a matter of conjecture, though in the Valley of the Mississippi we recognise the characters of a red sandstone deposit. The salt of Cordova, in Spain, and various points along the line of the Pyrenees, appears to lie in green sand; that of the Salzburg alps belongs to alpine limestone of the oolitic area, while in Sicily salt is found in sulphureous tertiary marl, and at Wielitzka it lies in tertiary strata containing a few shells.

Circumstances attending the Origin of the Saliferous System.

Its marine origin.

From the preceding statement we may confidently decide that the whole of the strata belonging to the saliferous system were deposited in the sea around the previously elevated lines of older rocks. The mechanical aggregates of sandstone, and clays, and marls, do not in general show us those exceedingly fine laminations and indefinitely numerous alternations of different materials which mark the coal deposits, they do not abound in such a multitude of spoils of the land, nor contain extended layers of the reliquiæ of fresh water. Had he never known of the local accumulations of fossil plants in the Keuper and variegated sandstones of the Continent of Europe, the English Geologist might have consistently doubted whether inundations from the land had ever disturbed the regular operations of the sea during this period. To explain this irregularity of distribution of terrestrial plants, it may be supposed that inundations from the land happened only in particular places along the margin of that ancient sea, or it may be said that the inundations being general, the growth of plants was limited. With respect to the accumulation of the rocks themselves, equal difference of opinion may be indulged; for if the remarkable absence, from the greater part of the area of the saliferous sytem, of any marine exuviæ in the mechanical aggregates might favour the notion of the materials being wholly derived from the land, yet the mere fact of the extraordinary and connected extent, the remarkable *uniformity of character of these extensive deposits*, even where the more anciently elevated strata round which they were evidently formed are of entirely different nature, and their apparent *independence* of these boundaries of their surface, seem to prove either 1. that the materials were collected by the action of the sea itself; or 2. that when brought into it by other agents, they were for very long times exposed to its equalizing action.

This long action of the waves upon the particles of the silicious and aluminous rocks and minerals which compose the mechanical aggregates and sedimentary deposits of the saliferous system, is also suggested by the amazing prevalence of the colour of peroxide of iron, which covers as a varnish so many of the particles; and it is confirmed by the discoveries of the organic remains, since these are of such a nature as to prove that during the saliferous period the whole living creation of the carboniferous period came to an end, and was replaced by several peculiar tribes which likewise finished their career and yielded to the more numerous races which fill the oolitic rocks.

Prevalence of magnesia.

The calcareous portion of this system presents us with even more decisive evidence, from its organic remains, of its marine origin, but the circumstances which permitted the accumulation of the magnesian carbonates of lime are in great measure unknown to us. That they were originally deposited in the same chemical condition as we now see them, without the subsequent aid of any igneous operations, is perfectly evident; and the occasional occurrence of *pebbles and shells* of the carboniferous system in the magnesian limestone, coupled with the known fact that certain beds of the carboniferous limestone contain a large proportion of magnesia, might lead us to conjecture that the one is derived from the ruins of the other. But, as Professor Sedgwick observes in discussing this subject, (*Geological Transactions*,) all the magnesian beds in the carboniferous limestone would be quite insufficient for the purpose, and the *crystalline character* of the Mansfield and other varieties of magnesian limestone clearly negatives this mechanical solution. Beds rich in magnesia alternate with others devoid of that substance, the same beds are in one tract magnesian, in another yield pure lime, and in general we must be content to shelter our ignorance under the statement that from some unknown cause the waters of the sea were then decomposed in such a way as to permit very generally the precipitation of united magnesian and calcareous carbonates—the possible circumstances of which must be intrusted to the examination of the Chemist.

Salt and gypsum.

The salt and gypsum usually associated in this remarkable system present also their difficulties. Not that it is hard to suppose the waters of the ancient sea to have been so evaporated as to permit first the crystallization of sulphate of lime, and finally of muriate of soda. But in this case we should expect to find almost uniformly over the whole area regular strata of gypsum below, and regular layers of salt above, while, in fact, we more commonly find salt in great broad masses rather than beds below, and gypsum in scattered masses above. A general drying of the waters in which the saliferous system was deposited is plainly inconsistent with probability; and we must have recourse to local causes, something analogous perhaps to those which influenced the deposit of primary limestone. It may be conceivable that the solubility of muriate of soda in water is capable of diminution through the admixture of other substances in the liquid, or through the effects of great pressure, or of pressure and heat combined; it may be maintained that the limited deposits of salt happened in separated lagunes of the sea, exposed to local desiccation, as perhaps in Cheshire. Mr. Lyell has still a different and less probable view of the subject. All these explanations assume that the salt was produced directly by *mere* crystallization, from waters almost perfectly analogous to those of the actual seas; an assumption strongly confirmed by the recent discoveries connected with bromine and iodine.

Further researches, both Chemical and Geological, must determine between these and other theories, and in particular, we must be more exactly informed of the ancient hydrography of the salt districts, which, in almost every instance, must have been very different from their present topographical features.

Table of the Organic Remains of the Saliferous System.

The asterisk distinguishes such as are known to occur in other systems of strata.

PLANTS.

Family.	Name.	Locality in Keuper.	Locality in Muschelkalk.	Locality in Pœcilitic Sandstone.	Locality in Magnesian Limestone.
Algæ	Fucoides Brardii				Frankenberg copp. slate.
	selaginoides				Mansfeld, ditto.
	frumentarius				Ditto.
	pectinatus				Ditto
	digitatus				Ditto.
	lycopodioides				Ditto.
Cryptogamia	Equisetum Meriani	Neue Welt near Basle.			
	*columnare	Würtemberg		Sulzbad, or Soultz.	
	platyodon	Franken in Würtem.

	elegans			Ditto.	
	rigida			Ditto.	
	acutifolia			Ditto.	
	pterophylla			Ditto.	
	Asterophyllites ? bulbosa				Thüringerwald.

The following plants, which are well known in the coal strata, occur in the lowest red sandstone. (Rothetodteliegende.)

*Lepidodendron Sternbergii	Hinkelheim in the Spessart.
*imbricatum	Werderbruck near Rothenburg.
*Stigmaria Veltheimiana	Magdeburg ?

Other vegetable relics at Amrode, Seibigkerode, between Friedeburg and Rothenburg, Kyffhaeuser, Meisdorf, Endorf.

The names in this list are taken from M Brongniart, who supposes the flora of the variegated sandstone system to be of a peculiar type It is certainly very analogous to that of the succeeding or oolitic epoch, by its pterophylla and equiseta, but the genus Voltzia is perhaps peculiar to it.

POLYPARIA.

Name.	Locality in Magnesian Limestone.
Gorgonia anceps, Goldfuss.	Glücksbrunn in Thuringerwald.
antiqua, G.	Glücksbrunn.
infundibuliformis. G.	Ditto.
*Calamopora spongites, G.	Ditto, (and Ural.)
Retepora flustracea, Phil.	Durham.
virgulacea, Phil.	Ditto.
Astræa pediculata, D.	

The absence of polyparia from the muschelkalk is one of the characters by which it approximates to the lias.

RADIARIA.

Name.	Locality in Keuper.	Locality in Muschelkalk.	Locality in Magnesian Limestone.
Ophiura prisca, Mün.	Vosges Mountains	Baireuth.	
loricata, G.	Schwenningen.		
Asterias obtusa, G.		Marbach.	
Encrinus moniliformis, Mil.		General in this rock.	
ramosus, Schl.			Glücksbrunn.
Pentacrinus dubius, Gold.		? Rudersdorf.	
*Cyathocrinus planus, Mil.			Durham.

ANNULOSA.

Name.	Locality in Muschelkalk.
Serpula valvata, G.	Baireuth.
colubrina	?

By its radiaria, amongst which no echinus is mentioned, the muschelkalk resembles the lias; those radiaria which lie in the magnesian limestone present greater analogies to the older rocks.

N.B. A species of terebratula ? is found in the rothetodteliegende at Mansfeld.

The general result of an examination of the fossil conchifera of the saliferous system, is, that in the upper strata a general analogy to the oolitic era can be recognised by the trigoniæ, plagiostomata, ostreæ, &c.; and in their productæ and spiriferæ the lower strata as distinctly claim affinity with the carboniferous *limestone*.

GASTEROPODA.

General Summary.

Plants	Marine	6	; wholly confined to the zechstein.
	Cryptogamia	23	; of which six are stated to occur in other systems of strata.
	Gymnospermia, &c.	17.	
Zoophyta	Polyparia	7	: all confined to the zechstein group; one found in another system of strata.
	Radiaria	7	; confined to the muschelkalk and zechstein; one repeated in carboniferous limestone.
Articulosa	Annulosa	2	in muschelkalk.
	Crustacea	1	
Mollusca	Conchifera plagymyona	32	; eight of these occur in England in magnesian limestone.
	mesomyona	32	; three of these occur in England in magnesian limestone.
	brachiopoda	28	; eight of these occur in England in magnesian limestone.
	Gasteropoda holostomata	17	; four of these occur in England in magnesian limestone.
	solenostomata	3.	
	Cephalopoda	6.	
Fishes		15	; four occur in England in magnesian limestone.
Reptiles		9.	
		205	; of which about thirty occur in England in magnesian limestone.

Disturbances of the Saliferous System.

In England dislocations of a very extensive nature are but rarely exemplified in strata more recent than the coal measures. It appears that this part of the surface of the Globe enjoyed a long and rarely interrupted immunity from those violent agencies which had previously shaken its strata into such disturbed positions. A few faults in the magnesian limestone range of Durham and Yorkshire, as along the line of the great whindyke through those Counties, in the country between Doncaster and Ferrybridge, and South of Doncaster, may be mentioned rather as exceptions to the general rule, effected in some indefinite portion of the long period succeeding the deposit of coal; and the curious parallel faults of Aust cliff on the Severn, which affect both the lias and red marl, deserve attention, in connection with the law formerly laid down of faults underlying depressed portions of strata. (p. 511.)

Neither on the Continent of Europe are the dislocations of the saliferous system so remarkable as those of the older strata. In the Vosges mountains we have, however, a splendid example of a dislocation on a great scale, by which, in a direction North-East and South-West, the lower strata of this system (*grès des* Vosges) are thrown up into bold mountains, while the upper beds of the same system (muschelkalk and keuper) are left several hundred feet below the magnificent escarpment. In fact, it appears that this eruption happened during the saliferous epoch, after the date of the grès des Vosges, and before the muschelkalk and keuper were deposited.

In the South-West of Brittany, in La Vendée, in Morvan, De Beaumont describes dislocations which appear to have preceded the lias; and from observations on the Böhmerwald and Thuringerwald it appears that the elevation of these ranges of mountains followed the saliferous epoch, and preceded the lias and oolites. Of the same era are some dislocations defining the primary ranges near Avallon and Autun.

Several cases, then, appear to show unconformity and interruption of continuity between the variegated marls and the oolitic formation above. But these are but local effects; parallelism of strata generally prevails between these contiguous systems, indicating freedom from general disturbance, and in some instances, especially in Somersetshire, the frequent changes of colour in the upper red marls, and finally the interposition of a purple or black marl, which is not more related to the lias than to the saliferous system, appear to show that even in the nature of the deposits there is no more decided difference between them than between any other successions of strata.

Oolitic System.

The oolitic system of strata has for the most part its ranges parallel, and its declinations accordant to the saliferous rocks, and was deposited in the same marine basins. The general character of the rocks, and the nature of the organic remains is however extremely different, but the change from the one system to the other, though seldom to be called gradual, is accomplished by remarkable repetitions. In particular, the muschelkalk of Germany and France represents, even in mineralogical characters, but most decidedly in its suite of organic exuviæ, the lias, which is at the base of the oolitic system. Through all the mass of the oolitic system, consisting of various limestones, clays, and sands, the most remarkable repetitions occur. The mass of lias contains beds very nearly approaching to the ferruginous inferior oolite; three or four separate beds of very similar oolite, several beds of sand and sandstone also remarkably analogous, and many thick strata of clay hardly distinguishable except by their organic reliquiæ, make up this vast argillo-arenaceo-calcareous mass, of which the top changes, by repeated introductions of green sand layers, to the real cretaceous system, as the bottom has been before shown to be connected with the saliferous group.

The composition of this system varies much in different Countries of Europe, according, probably, to the differences of depth of the original waters, proximity to land, to mouths of ancient rivers, &c. In consequence, while on the border of Swisserland it is almost wholly calcareous, in Westphalia and in England its limestones are much intercalated with clay, and occasionally with carboniferous sandstones and shales, hardly to be distinguished from those of the older coal strata. A remarkable absence of metallic substances is a character of the calcareous portions of this system (excepting the lias) in all its extent.

The most distinct classification of the oolitic system will be obtained from the combined section of the English series; for though the total thickness of the deposit is perhaps greater in the South East of France and in Swisserland, the number of divisions is there less, the mass more uniformly calcareous, and the parts less characteristic.

The oolitic system of England everywhere admits of the following mode of subdivision, though in some tracts particular groups are concealed by unconformity or entirely wanting. The groups are placed as they occur in nature, or the series is descending.

5. Wealden formation.	A series of clays, sandstones, and limestones, mostly of fluviatile origin, and containing remains of land and fresh-water animals and plants, deposited in estuaries or other local hollows of the really marine portion of the oolitic system.
4 Upper or Portland oolite formation.	Calcareous, sometimes oolitic rocks, associated with green and irony sands, resting on blue clay, altogether marine deposits. When the Wealden formation is absent (as happens in the greater number of instances) this terminates the whole system, and graduates into the cretaceous rocks above.
3. Middle oolite or coralline formation.	Consisting of oolite and other limestone strata, included in calcareous gritstones, and resting on blue clay and calcareous gritstone: altogether marine deposits.
2 Lower or Bath oolite formation.	Consisting of two or more strata of oolite, with other calcareous beds, and alternations of sands and clays, which in particular districts enlarge themselves into real coal tracts. Altogether marine and littoral deposits.
1. Lias formation.	Consisting principally of argillaceous clays, more or less laminated, and including, especially in the lower part, layers and nodules of generally argillaceous limestone, and in the upper part bands and strata ferruginous, calcareous, and arenaceous, which strongly resemble the bottom of the lower oolite formation.

Oolitic System.

A further analysis of these formations presents us with the following details.

5. Wealden formation of Kent, Sussex, and Hampshire.			*Weald clay.* Thick blue clays, generally destitute of organic remains, except in certain calcareous beds, which contain fresh-water shells.
			Hastings' sands. Thick series of sandstones, with partings of clay, and subordinate beds of limestone, with bones of saurians, fluviatile shells, and land plants.
			Purbeck beds. Blue clays and laminated limestones with fluviatile shells.
4. Upper oolite formation of Portland, Wilts, Bucks, Berks, &c.			*Portland oolite.* Oolite and earthy and compact limestones with marine shells, and layers of nodular chert.
			Shotover sand. Calcareous sand and concretions.
			Kimmeridge clay. Thick blue clay, bituminous, with septaria and marine remains, and especially in the lower part, bands of sandy concretions, thus establishing a gradation to the next system.
3. Middle oolite formation of Oxford, Berkshire, Yorkshire, &c.	Coralline oolite group.		Upper calcareous grit, with marine fossils.
			Coralline oolite, so named from two or three separate beds of irregular occurrence, rich in zoophytic exuviæ. In the lower part the beds alternate with those of the next rock; all of them contain marine exuviæ.
			Clay 10 feet. Lower calcareous grit, with marine shells, graduating below into the Oxford clay.
	Oxford clay group.		Oxford clay, with septaria, fossils, &c.; the lower part a subordinate bed, called
			Kelloway rock, which is a calcareous grit, (rarely oolitic,) very rich in fossils.
			Blue clay dividing Kelloway rock from the cornbrash.
2. Lower oolite formation in Gloucestershire, Oxfordshire, and Northamptonshire	N. B. All this part of the series is differently composed in Yorkshire and the North of Scotland.		Cornbrash limestone, a coarse, shelly rock of variable and small thickness, but remarkable continuity.
		Forest marble group.	Sand with concretions of sandstone and nodules of fissile arenaceous limestone.
			Coarse shelly oolite, in some places slaty
			Sandy clay or grit.
			Blue clay.
		Great oolite.	A calcareous and mostly oolitic rock, of variable thickness and changeable nature, the upper beds shelly.
		Fuller's earth group.	A series of marls and clays with included beds of soft marly or sandy limestones and shells.
		Inferior oolite.	A coarse, often very shelly rock of limestone, irregularly oolitic, occasionally interlaminated with sand, especially in the lower part.
			Ferruginous sand with concretionary masses of sandy limestone and shells.
1. Lias formation in Yorkshire, Northamptonshire, and Somersetshire.			Upper lias clay or shale, full of belemnites and other fossils, intercalated with or graduating to the sand above, and in some cases containing nodules and bands of limestone.
			Marlstone. A suite of calcareous, sandy, and irony beds, very rich in fossils, and much analogous to the lowest bed of the lower oolite formation.
			Lower lias clay or shale, full of fossil remains, interlaminated with bands and nodules of limestone, especially in the lower part, where a collection of these layers constitutes the lias rock.
			Lias rock. A suite of laminated limestones, with partings of clay, blue, grey, and white, the former in particular containing gryphites and other shells; the latter usually devoid of organic remains. This rock is sometimes consolidated into a united mass, and sometimes divided into separate portions. It rests on the red marl in the North of England, and on blue, black, or purple marls, which cover that formation in the South of England.

The lias formation is observed on the Southern coast of England, at Lyme Regis, from whence passing under the unconformable green sand of Blackdown, and surrounding the irregular elevations of carboniferous limestone in Somersetshire, it ranges uninterruptedly by Bath, Gloucester, Leicester, Newark, and Gainsborough, to the Humber. At this point the course of the oolitic system is very much narrowed by the overextension of the chalk; and at Bishop Wilton the chalk rests on the lowest part of the lias formation, which has a superficial breadth of only a few yards. It, however, expands again towards the North, and shows itself very completely developed on the coast of Yorkshire. Detached portions of this formation accompany the saliferous system in Glamorganshire, and lie unconformably in the hollows amongst elevated ridges of carboniferous limestone.

Through the whole of this range some general physical features, almost constant mineralogical qualities, and prevalent species of organic reliquiæ, fix such a decided character upon the lias formation as to establish a good geological horizon for the guidance of the English observer.

The country which it occupies is in general a broad vale at the foot of the escarpments of oolite, and terminating towards the red marl by a very connected range of uniform low hills. A considerable portion of the steep slope of the oolite escarpments is occupied by the lias; and in the Midland Counties, particularly, owing to the action of currents of water, detached portions of oolite crown the summits of many insulated masses of the upper lias shales.

From the coldness and stiffness of the soil, much of the surface of the lias clays remains in pasture, for which it is particularly well adapted; and where the plough has in former times been employed, the land is thrown up into very high ridges for the sake of surface drainage. Water is scarce in this tract, and, because of the abundance of pyrites, often sulphureous or ferruginous, or impregnated with purgative salts, as sulphate of soda.

A general tendency to an argillaceous type belongs even to the limestones of the lias formation, and its clays more frequently exhibit a schistose structure than the other clays of the oolitic system. Layers and masses of jet are frequent in it, especially in the Northern part of its course; pyrites is one of its most abundant productions, especially in connection with ammonites and other shells, and sulphur in some parts is so prevalent as to furnish a valuable manufacture of alum. Many fruitless trials for coal along the line of the lias clays are upon record, to serve as a warning to those unacquainted with Geology.

Very remarkable organic exuviæ belong almost equally to every part of the English lias. Skeletons of saurian and chelonian reptiles, several species of scaly fishes, abundance of ammonites and belemnites, plagiostomata, gryphææ, &c. and considerable quantities of the wood of coniferous trees, enable the Naturalist to form very reasonable views of the state of the ancient land and sea when this formation was in progress, and serve not only to identify it in all parts of England, but even over a large part of its extent in France and Germany.

Nevertheless, there are important geographical peculiarities connected with the lias of England, which deserve a short analysis, the better to enable us to perceive the circumstances under which the ancient sedimentary deposits of the sea took place.

Lias in Yorkshire.

The section of the lias, as it exists in Yorkshire and Lincolnshire, is peculiarly instructive and complete, and forms an excellent type with which to compare the detached portions of the formation in North Britain and the South of England. We shall take the groups in the ascending order of their antiquity.

Lias limestone. The calcareous beds included in this division are in the North of England very distinctly divided into two or more portions separated by considerable thickness of clay.

1. The lower limestone, 10 to 20 feet thick, is not traced further North than the Humber. It consists of compact blue or grey limestone, generally laminated and shelly, with partings of whitish clay or marl. It rests immediately upon the red marl and gypsum.

2. Clay, 50 to 100 feet, with layers of nodules, often septariate, full of pentacrinites, ammonites, plagiostomata, &c.

3. Upper lias limestone, 12 to 20 feet, in rough, shelly, coarsely laminated beds, separated by partings of clay. The colour usually brown, but in wet pits and before exposure to the air internally blue. But the most remarkable character of these beds is the astonishing abundance of gryphæa incurva which they contain, or rather of which they almost wholly consist. In several parts of Lincolnshire the roads are mended with the most beautiful specimens of this fossil, and for miles together hardly any other shells can be collected from this part of the lias.

Lower lias clay or shale, 300 to 500 feet thick, a dark homogeneous clay or shale, with many layers of argillo-calcareous nodules, seldom containing shells, and in the lower part rough sandy beds. Coniferous wood, pentacrinites, plicatulæ, gryphæa Maccullochii, pinna folium, and several ammonites, &c. occur in this stratum, but in it organic remains are not particularly abundant, and neither belemnites, terebratulæ, nor saurians are so plentiful as in the beds above. No alum is made from this part of the lias shale.

Marlstone series, 100 to 150 feet, consisting of highly arenaceous shales, and laminated sandy limestones of brown, greenish, or grey colour, succeeded above by several bands of nodular ironstone, the whole series particularly abundant in shells, besides producing beautiful stellerida, annulosa, and fishes. Several species of terebratulæ, cardium truncatum, dentalium giganteum, &c. appear almost confined to these strata, which likewise contain gryphææ, pectines, plagiostomata, terebratulæ, and modiolæ, not distinguishable from the ordinary fossils of the oolite. The marlstone beds are in fact the first term of the oolitic deposits, interpolated among the last terms of the lias, and, according as the clay above them is attenuated or developed, they may be ranked with the oolitic, or the lias formation. In the North of England, the former mode of arrangement *must* be adopted, but in the South, the latter has been often followed.

The upper lias clay or shale, 50 to 200 feet in thickness, is the aluminous rock of Yorkshire, and passes by intermixture into the marlstone series below, and by a gradual change into the analogous sandy beds of the oolites above.

It contains a multitude of layers of argillo-calcareous nodules mostly aggregated round ammonites and other organic bodies, and these are particularly remarkable and of larger size in the lower part of the shale, which also is much harder than the rest. A profusion of ammonites, belemnites, and nautili, accompanied by aviculæ, inocerami, amphidesmata, &c., besides abundance of ichthyosauri, and plesiosauri, jet, and remains of coniferous wood, enrich this interesting rock. Its thickness is variable, amounting to 200 feet on the coast, but diminished to 50 feet, or even less, in some of the Cleveland hills, where also the usual smooth homogeneous texture of aluminous shale is changed to a decidedly sandy composition.

Li Mid Coun

Proceeding to the South, we find the characters of the lias formation of Yorkshire maintained with considerable exactness through the Counties of Nottingham, Lincoln, Leicester, and Rutland, into Oxfordshire. The section from Lincoln to Gainsborough shows clearly the upper lias clay, marlstone group, lower lias clay, gryphite limestone, and laminated limestone, all superimposed on gypseous red marl. In the vale of Belvoir, likewise, through Rutland, and as far as the centre of Oxfordshire, we have the lower laminated limestone (1.) surmounted by a thick clay, (2.) in which lie gryphitic beds peculiarly shelly, which Mr. Conybeare calls *upper lias* beds, and which correspond to the gryphitic beds of Lincolnshire. Still higher, are beds of green or brown marly sandstone, with terebratulæ, pectines, belemnites, and other shells, which are always ferruginous, and, in Rutland particularly, laminated and entirely similar to some of the marlstone beds of Yorkshire. Above these, in the same tracts, lie 100 or even more feet of clay, often forming insular hills between valleys of marlstone, and upon the whole the ferruginous sand of the inferior oolite.

If any doubt has at any time been raised as to the real distinction in this country of upper lias clay, marlstone, lower lias clay, and double course of lias limestone, it has probably arisen from the extreme resemblance of the ferruginous marlstone of the Vale of Belvoir which divides the upper from the lower lias clay to the ferruginous sandstone which is the general floor of the oolitic rocks. In Rutland, however, the distinction is perfectly evident.

Lias of the Cottswold.

Through Oxfordshire and Gloucestershire the upper lias clay continually becomes thinner, and the marlstone beds in consequence approach nearer to the sand of the inferior oolite. It is no wonder, therefore, that they should be in these Countries sometimes confounded. But the section of Painswick Hill, near Stroud, adduced by Mr. Conybeare, (*Geology of England*, p. 252.) sufficiently proves that the same principle of classification applies to the lias below the Cottswolds, as well as to the North-East moorlands of Yorkshire. In fact, by merely taking the argillaceous beds which in this section separate the sands of the oolite from those of the marlstone, and calling them upper lias clay, the accordance with the Yorkshire section is perfectly evident. This question has been effectually settled by Mr. Lonsdale's recent and most valuable investigation of the Cottswolds. That excellent observer has clearly established the identity of the lias system of Gloucestershire with that of Yorkshire, in general terms; at the same time defining the amount of topographical difference which principally affects the upper lias shale.

In the Southern parts of Gloucestershire, and in the vicinity of Bath, the upper lias clay becomes still more attenuated, and the marlstone beds more divided and mixed with the clay. Mr. Smith gave the name of marlstone to the laminated stony beds full of pectines and other shells which are found in the Somerset canal and other places, twenty feet or less below the sand of the inferior oolite, as may be noticed in his sections. In several places, these beds, from the deficiency of the clay above, are brought nearly into close contact with the sand of the inferior oolite.

Whether this distinction of marlstone beds can be carried further South into Dorsetshire does not yet appear.

From Mr. Lonsdale's Essay in the *Geological Transactions*, we find the lias limestones to be thus arranged in the descending order.

	Feet.
Blue lias. Consisting of beds of greyish argillaceous limestone, varying in thickness from 2 to 18 inches, and separated by others of blue marl which are generally less than 6 inches thick, but sometimes more than 2 feet	50 to 60
White lias. Thin strata of yellowish white argillaceous limestone, with partings of pale brownish clay	10
Lias lower marl. Dark grey marl with calcareous concretions	20

Organic remains of ammonites, belemnites, pectens, oysters, &c. though most abundant in the blue lias, are more or less diffused through all the beds.

Combining the section of the North of England with Mr. Lonsdale's and Mr. de la Beche's sections of the lias in the vicinity of Bath and Lyme, we shall have the following general table of the complete type of the English lias.

1. Upper lias clay, marl, or shale..	Upper lias shale (Phillips.)
2. Marlstone beds.	
3. Middle lias clay	Upper lias marl. (Lonsdale.) Lower lias shale. (Phillips.)
4. Lias limestones and marls ...	Gryphitic and laminated lias of North of England. Blue and white lias of Bath.
5. Lower lias marls	Of Lyme Regis and Bath.

These lower marls are thus described by De la Beche, at Culverhole, near Lyme, (section descending.)

	Ft.	In.
Dark marl	3	0
Earthy dark grey limestone	0	10
Dark grey slaty marl..............................	5	9
Irregular light grey limestone	0	10
Dark slaty marl...................................	1	4
Compact grey limestone............................	0	10
Dark slaty marl, which rests on the light bluish green beds belonging to the upper part of the new red sandstone system	7	0
Total...	18	10

Lias in North Britain.

Mr. Murchison's *Memoirs on the Oolitic Deposits of North Britain*, most clearly prove the existence of well-characterised lias shales, much like those of the Yorkshire coast, in Pabba, Skye, and other of the Western Isles, and the organic remains which he collected there are of the usual English types. Lias occurs also on the North-East coast of Ireland, as at the Giant's Causeway, with ammonites and belemnites.

The lias in South Wales is a singular extension of the formation among the dislocations of the older carboniferous system, nearly analogous to its appearance among the sandstones and slates of Scotland. The Valley of the Ely, in South Glamorganshire, exhibits several uptillings of lias, commencing about five miles West of Landaff, whence, with some interruptions, they accompany the Ely to its junction with the Channel near Penarth Point. It again appears in Barry Island, and continues to skirt the coast in a Westerly direction nearly to the mouth of the Ogmore river, forming a range of bold cliffs, among which is the little harbour of Aberthaw, celebrated for the lime which it exports. (Conybeare, *Geology of England*.)

Lias in France and Germany.

We may now turn our attention to the general types of lias presented in the North and South-East of France, and in various parts of Germany.

As in England, so generally in these Countries, the lias is deposited conformably to the saliferous system, but in Brittany and around the plateau of primary rocks in central France, especially about Autun, the oolitic system often touches the granitic series without any interposition of red sandstones. In the district which borders that plateau on the East, between Chalons and Autun, the oolitic rocks are considerably developed with lias at the bottom, and all based upon gypseous red marl; but the lias clays are here almost wholly deficient, and the formation consists only of the gryphitic limestone, with its partings of clay. The abundance of gryphæa incurva, and other characters of the stone, strongly remind the traveller of the analogous beds in Lincolnshire. The lias and oolites are so closely allied that Desnoyers, in his description of this tract, hesitates even to distinguish the former as a fourth stage of the calcareous or oolitic system.

South of the Ardennes mountains by Luxemburg, Metz, and Nancy, the lias exhibits more developed characters. Immediately upon the Keuper marls rests a considerable bed of sandstone, white, yellow, or rarely brown, sometimes solid, and sometimes friable; gradually passing into the lias beds above. From its abundance under and around the fortress of Luxemburg, it receives in that Country the name of *grès de Luxemburg*.

The proper gryphitic lias limestones succeed and cap most of the plateaux of grit. The beds are bluish and compact, and alternate with grey friable marls.

Above are grey marls and marly grits, which correspond to the lias clays and marlstone of England; and these are followed by the ferruginous sandstones which form the general floor of the oolitic system.

In Würtemberg, and, perhaps, generally on the German side of the Rhine, the lias has more of the character of the Fnglish series both as to mineralogical composition and organic remains. In particular, the saurian reliquiæ, so abundant in the lias clays of England, are all found in those of Boll and other parts of Würtemberg, and with some additional species have been described by M. Jäger, of Stuttgart. Fine specimens of saurian animals occur in many of the museums along the Rhine. But, perhaps, the most remarkable accordance between the series of Germany and that of England, is observed at Banz near Coburg, where the Maine crosses the Northern extremity of the Franconian range of oolites. Here Mr. Murchison has observed the following section.

Sandstone cap of the lias	300 feet thick.
Upper lias shale of Yorkshire..............	40
Marls and marlstones	150
Lower lias shale, with compact lias and ammonites Hawkerensis, near the top	300
Gryphite limestone	
Gritstone..................................	
Keuper formation	

At this place the most astonishing profusion of saurians, fishes, crustacea, ammonites, nautili, and belemnites, as well as pentacrini, gryphites, and other fossils, occur, and many of them remarkably agree as to their place in the strata with the arrangement of the same species in the beds of the coast of Yorkshire.

Lias shales occur below the Alpine or Jura limestone of Swisserland and Savoy, and occasionally, as at Meyringen, Bex, the Mont Joux, produce some of the characteristic ammonites and belemnites of the English lias. In the Valley of the Arve, in particular, the argillaceous beds of lias are immensely thick, and owing to the igneous agency, once so powerfully excited beneath the Alps, have a schistose character strongly assimilating them to the primary slates. Whether the slates of the Valorsine belong to the same era is, perhaps, not yet ascertained; but if this should be proved, the vegetable remains which they contain, being identical with those of the carboniferous epoch, would indicate that these regions enjoyed a particular immunity from the causes which, in all other instances yet examined, had wholly destroyed the plants which grew in the carboniferous epoch, and covered the earth with cycadeæ and other entirely new types of vegetable life.

Lower Oolite Formation.

The uninterrupted range of this formation through Dorset, Somerset, Gloucestershire, Oxon, Northamptonshire, Rutland, and Lincoln, to the banks of the Humber, may be seen on the Maps of Mr. Smith or Mr. Greenough. Beyond the Humber it is concealed for a short distance beneath the overlying chalk, but emerges again, and occupies a vast breadth in the Eastern part of Yorkshire. In Sutherland, and in some of the Hebrides, and particularly in Skye, it has been traced by Mr. Murchison.

It occupies, through all its course in England, an elevated range of hills with bold escarpments to the West or North-West, a gentle slope to the East or South-East, and deep valleys of denudation which often, by descending to the lias clays, furnish most complete information as to the relations of the two formations. The surface of the calcareous portions is dry and bare of trees, and wells sunk therein often reach a very considerable depth, while upon the alternating clays the soil is cold or wet, and, in general, much covered by woods. The fertility of the district is below the average of the secondary strata. The highest point of the range in the South of England is Cleeve Pipard Hill, near Cheltenham, 1134 feet above the sea, and in the North of England, Botton Head, near Ingleby in Yorkshire, 1485 feet; but in these cases about two-thirds of the height consists of the lias clays.

The more ordinary altitudes of the oolitic range in England are 700, 800, and 900 feet, varying according to the Westward extension of the hill, the thickness of the base of lias, and the pile of incumbent strata.

Escarpments of oolite.

Certainly, this regular and continuous range of oolites, with so nearly uniform an elevation of escarpment, is one of the most characteristic features of English Geology, and furnishes matter for profound reflection. For like the parallel, equally continuous and regular, and but slightly lower range of chalk, its elevation seems not at all due to local disturbances, but rather appears to indicate a general intumescence of the land in the direction of these ranges. The low vales of lias, Oxford clay, and Kimmeridge clay, which intervene between the lower, middle, and superior oolite ranges, have undoubtedly been caused, at least in part, by the erosive action of water; but to whatever extent we apply this principle in explaining the present inequality of the earth's surface, and whatever aid we receive for the established data of local elevation, these limited agencies always leave unexplained the general fact, *viz.*, the regular altitude of continuous ranges of hills with uniformly declining planes, and no particular marks of convulsion, which overlook extensive undisturbed plains of older strata.

The vicinity of Bath, where Mr. Smith began his important researches, furnishes the general type of the lower oolite formation; and, with some modifications, the series of strata here presented, as detailed by Mr. Smith and Mr. Lonsdale, is found to be almost universally reconcilable with the phenomena of the other oolitic districts. The variations observed are principally caused by the interpolations of a larger proportion of arenaceous, argillaceous, and carbonaceous beds, so as in extreme cases to change the calcareous section of Bath into a coal field, with subordinate beds of limestone. Such is especially the case in the Eastern moorlands of Yorkshire, at Brora in the Hebrides, and in the gorge of the Weser at Minden, as observed by Mr. Murchison.

The table of classification given above, will make known the order of succession of groups recognised in this formation, and we shall now proceed to point out their characters and notice their variations more exactly.

Inferior oolite group.

The SAND which is the base of the inferior oolite group in the vicinity of Bath, possesses, in general, only a slight degree of cohesiveness, but in places passes into a friable sandstone. It is micaceous, of a yellow colour, and contains irregular courses of calcareous concretions called sand burrs. These nodules are often aggregated round ammonites and other organic bodies. The thickness of this bed sometimes amounts to 70 feet.

The inferior oolite varies in thickness, in some places being 60 feet, in others considerably less. The rock, according to Lonsdale, admits of being characterised in three portions, the lower one 6 feet, hard, of a brown colour, abounds in casts of trigoniæ, limæ, trochi, &c., and is seen in many sections reposing immediately on the sand. The coated muscles, as they are termed, are found in this bed, and the bed which in the descending quarries yields so immense an abundance of species is apparently of the same date. The middle division, 10 feet, is a rubbly stone; principally consisting of crystallized carbonate of lime, through which the organization of astreæ may be clearly traced. It is, therefore, a coral bed, and as might be supposed is of irregular occurrence.

The upper portion of the rock, 40 to 50 feet at the utmost, contains the workable freestone or oolite of this rock, the upper part, in particular, cannot be distinguished in specimens from the great oolite above. The lower beds are more sandy, browner, and less oolitic.

The fuller's earth group.

The fuller's earth group, so named from the occurrence in it of limited beds of that substance, is a thick argillaceous deposit with a few layers of nodular limestone and indurated marl, occurring on the hill sides of Bath, and distinctly separating the inferior from the great oolite. The following is Mr. Lonsdale's summary of these beds.

	Feet.
4. Blue and yellow clay with nodules of indurated marl	30 to 40
3. Bad fuller's earth	3 to 5
2 Good fuller's earth, brown or blue	2½ to 3
1. Clay containing beds of bad fuller's earth and layers of nodular limestone (fuller's earth rock) and indurated marl	100

The great oolite rock.

The great oolite rock contains, besides the more perfectly oolitic parts, which hold few shells and furnish the best freestone, a great number of beds, in which the oolitic structure is less evident or even wanting, and which are more or less filled with remains of shells, corallines, &c. These coarser portions of the rock lie at the top and bottom, and enclose the purer oolite between them.

The lower rags consist of several beds of coarse shelly limestones 10 to 40 feet; the lowest bed of it which rests on the fuller's earth group is fine-grained and scarcely oolitic.

The oolitic beds in the middle are very variable in thickness and quality. On Combe Down the thickness sometimes amounts to 30 feet. The stone when taken from the quarry is quite soft, and holds so much water as to be beaten to a pulp by the hammer. After being thoroughly dried it will absorb more than one-seventh of its weight of water, but by long exposure it grows harder and less absorbent. It will not stand the sea air, though in the neighbourhood of the quarries it is very durable.

The upper rags, 20 to 55 feet, consist of alternating beds of coarse shelly limestones, tolerably fine oolite sand, tough, brown, argillaceous limestone. The shelly beds were used by the Romans in their buildings at Bath, and are thought to be very durable, but are difficult to work. Some of these beds are full of millepores and other polyparia and species of echini, and a profusion of minute univalve and bivalve shells. They often exhibit that peculiarity of internal lamination called false bedding, when the ingredients of the stone form layers inclined to the plane of stratification.

The forest marble group.

The forest marble group admits of the following subdivision in a descending order:

	Feet.
6. Clay with occasional laminæ of grit	15
And at Norton St. Philip a layer of rubbly indurated marl abounds with fragments of a small oyster and terebratula.	
5. Sand and nodules, or beds of calcareous gritstone	40
The sand is reddish-yellow or white, pure or mixed with clay, or lime. The gritstone, usually of a brown but sometimes of a blue colour, exists in spheroidal masses which have a laminated structure parallel to the stratification, and occasionally can be split into flags.	
The fracture often shows shining facets of interposed carbonate of lime. Organic remains are generally rare in these beds, sometimes particularly abundant.	
4. Clay with thin slabs of stone and laminæ of grit	10
3. Coarse oolite, or shelly limestone (forest marble) full of fragments of wood and shells, especially ostreæ and plagiostomata, bones, teeth, &c. The majority of the beds have a fissile structure, and can often be split into thin flags, or tiles, oblique to the plane of stratification.	
Thin partings of clay generally divide the beds.	
2. Sand, or sandy clay and grit	10
1. Pale blue or grey clay, enclosing thin slabs of tough brownish limestone and laminæ of calcareous sandstone or grit. Thickness variable	5 to 40

The cornbrash.

The cornbrash consists of numerous rubbly beds of coarse limestone, mixed with clay, altogether 10 to 15 feet thick. The beds or rather nodules are extremely irregular, and of different colours, but they are pretty uniformly composed of tough granular limestone, and abound with terebratulæ, avicula echinata, isocardia, amphidesmata, &c.

In tracing the lower oolite formation to the South from the Bath district, the inferior oolite is found to become more ferruginous, (Sherborne,) and with its subjacent sand to cap the lias as far as Bridport, but the great oolite soon "thins out," while the forest marble group thickens and becomes predominant. The cornbrash retains its usual characters and fossils.

Lower oolites of Yorkshire.

In the district lying North of the Humber the lower oolitic system assumes entirely new characters which will require separate consideration. The beds seen in the imperfect exhibition of these oolites near Cave, where they divide the lias from the Oxford clay, are, the sand of the inferior oolite covered by shelly and oolitic beds, a continuation of the oolite of Lincolnshire, and above them a thin bed of pale blue clay. They are here much diminished in thickness, and, though burnt to lime, somewhat debased in purity. On the banks of the Derwent, the lias is surmounted by the same simple series, with the addition of beds of calcareous flagstone above. Further along the range, at Brandsby and Wiganthorpe, the series is expanded by the interposition of beds of sandstone and shale, with a thin band of coal between the sand which caps the lias, and the shelly limestone which here represents the oolite of Lincolnshire. Above the limestone runs a band of pale blue clay; and upon this rests a succession of beds of sand and sandstone, enclosing spheroidal concretions of calcareous sandstone with glistening facets, often blue in the centre and full of shells, some of which resemble those of Stonesfield. Beds of sandstone, shale, land carbonaceous matter are also interpolated above this slaty rock. The oolite here is hardly deserving of that name from its lithological character, for though this appearance sometimes presents itself, the greater part of the stone is a coarse, granular, shelly limestone, with imbedded shells, &c. It is, in fact, the oolite of Cave still more degenerated. The series of sandstones and shales with coal which here overlies the sandstone cap of the lias, has been supposed analogous in position to the fuller's earth group of Bath, (the similar series which overlies the limestone beds corresponds to the interval between great oolite and cornbrash,) and as we proceed Northwards both series increase immensely in thickness, so that the lower one reaches 500 feet, and the upper one 200; and as, from local circumstances, the coal, though never more than 16 inches thick, is worth working, these moorlands assume the appearance of a true coal field, with subordinate beds of very coarse shelly limestone. It requires, indeed, very close observation to trace the thin limestone beds across these vast moors, and amidst such a number of sandstone beds. They are best studied on the coast. The sandstone upon the lias is here a variable rock often coarse and fragmentary, sometimes with the characters of ordinary sandstone, but generally subcalcareous, ochraceous, and full of shells and casts. At Blue Wick, near Robin Hood's Bay, it presents a double band of fossil-bearing beds, the lower one gradually passing to the subjacent lias. The limestone appears with different aspects at different points. Under Gristhorp cliffs it recalls pretty exactly the oolite of Cave, but at Scarborough, Cloughton, Hawsker, Sneaton, &c., it is a very different rock, coarse, fragmentary, and mixed with veins of earthy and argillaceous oolite, so as to be scarcely fit to be burned to lime. In the Staintondale cliffs it is a double band; at Whitenab it is covered by calcareous sandstone slate, in which glistening facets, like those in the stone of Brandsby and Wittering, occur. Only one seam of coal is worked in the district, and it lies beneath the limestone. The cornbrash appears on the coast, also, in a debased but recognisable form. The fossil plants which accompany the coal seams and sandstones, may also be detected in the limestones and calcareous slates both on the coast and at Brandsby; and it is worthy of particular attention, that both at Collyweston and at Stonesfield, several of these plants occur in the slate, as brachyphylla, ferns, and cycadites. No marine exuviæ have yet been found in these coal grits or shales, but some bivalves resembling anodon, which perhaps were swept down with the ferns, equiseta and cycadeæ, are found at Gristhorp. In several places, a particular part of the section of lower carboniferous sandstones, exhibits the remarkable phenomenon of equiseta standing irregularly erect over considerable areas in a bed of sandstone which rests upon shale.

This is, therefore, truly a coal field of the oolitic era, produced by the interposition of vast quantities of sedimentary deposits brought down by floods from the land, between the more exclusively marine strata of the ordinary oolitic type. We may believe this to be a case of a littoral deposit of oolite, and should naturally derive from that supposition, the debasement of quality and attenuation of thickness of the shelly limestones, in proportion as the spoils of the land brought down into the sea were more abundant. Whatever the causes were which produced these effects, they were not entirely local. The Yorkshire oolitic district is indeed the only tract yet investigated in England which exhibits these effects in a striking manner; but attentive consideration of the phenomena presented by the rag beds of oolite and coarse shelly beds of forest marble near Bath, and still more the wavy surface and vegetable fossils of some kinds of the sandstone slate of Ridge, Stonesfield, and Collyweston, will lead to the conclusion that these portions of the oolitic formation were deposited within the influence of the littoral agitation of the sea. (Mr. Scrope has presented a notice of this subject to the Geological Society.)

Another fact is important. The extensive additions of terrestrial plants and sediment are confined to the intervals between the sand which is the base, and the cornbrash which is the cap of the lower oolite formation.

Mr. Murchison's examination of Brora and other points in Sutherland, and of the Western coast of Scotland, has proved the extension of the carboniferous system of the Yorkshire oolites into these Northern regions, and it is interesting to observe that there, as well as in Yorkshire, the interpolations occupy the same limited space in the section.

The following short summary of the beds in these Countries will prove this point:—

Section of Brora.

Middle oolite formation consisting of ……	Calcareous grit and Oxford clay.
Lower oolite formation consisting of …….	Shelly limestones representing cornbrash and forest marble. Alternations of sandstones, shales, and ironstones with plants. Ferruginous limestones, blue in the interior, with fragments of carbonized wood and abundance of shells. Sandstones and shales of great thickness in frequent alternations with plants, having *in the upper part* two beds of coal, of which the upper one is 3 ft. 8 in. thick, the lower one, not worked, 1 ft. 4 in.
Lias formation with fossils of the Yorkshire lias.	

North-East Coast, Isle of Skye.

Sandstone series.
Shelly limestone.
Sandstones and shales of great thickness, with obscure impressions of plants and abundance of carbonaceous matter.
Calciferous sandstone beds, with small nodules of indurated limestone grit, with fossils and thin layers of shale with belemnites.
Blue shale (upper lias shale of the Yorkshire coast) with small blue calcareous concretions, belemnites, &c.
Sandstone with concretionary nodules and fossils of the marlstone series.
Lias shale.—*Geological Transactions, New Series.*

The same Geologist has found a considerable analogy to these phenomena in the section presented by the gorge of the Weser, where that river escapes through the Porta Westphalica into the plains of Northern Germany. How unlike to the general type of the oolitic formation of the German and Swiss Jura!

Having thus produced the two most contrasted types yet discovered of the lower oolite formation, and by their comparison put a severe check upon the doctrine of universal formations (if such was ever entertained) among the secondary strata, it will be useful to state the leading features of this formation in the intermediate parts of its range in England, and thus to ascertain the parts which vary, and the method of their variation. To do this with entire satisfaction is not easy, and indeed requires more data, yet the curious fact of the continuity of the cornbrash above, and of the lower oolite sand below, from one end of England to the other, by furnishing every where exact limits to the formation, very much abridges the inquiry and diminishes the chances of error. In the long range from the coast of Dorsetshire to the coast of Whitby, the character of the lower sand varies, yet not so much as is common to sandstones, the principal difference consisting in the colour which is occasioned by the degree of oxidation of the iron. Through Oxfordshire, Rutland, Lincoln, and the Southern part of Yorkshire, it is a very dark brown ferruginous rock, whence it is often called "gingerbread stone," frequently enclosing shelly concretions, (Banbury,) occasionally enveloping beds of limestone, and sometimes (Northampton, Rockingham) interlaminated by white beds of oolite. The quantity of oxide of iron is sometimes so considerable as to divide the mass of the rock into a multitude of ochraceous cells or "iron boxes." In some places, especially in Lincolnshire, it consists of an alternating series of white and brown sand.

With respect to the cornbrash it is sufficient to say, that though so unimportant a rock in other respects, it is probably more continuous, and more uniform in its character from Dorsetshire to the Humber, as may be seen in Mr. Smith's Maps, than any other member of the lower oolitic formation except the sand of the inferior oolite.

Lincolnshire.

Lincolnshire presents the following section of this formation: (observations made in 1821:)

Cornbrash full of its usual fossils.
Clay thin.
Thin shelly beds *in one locality*, somewhat resembling the blue beds of Farley near Bath.
A considerable thickness of clay ground, presumed by Mr. Smith to include the forest marble system of Wiltshire.
Sandy laminated stone, in a few localities South of Lincoln.
Thick, apparently undivided, oolitic rock, very productive of organic remains, with polypiferous beds on the top.
In the upper parts of this rock, false bedding is frequent, coarse shelly rags abound, good oolite is dug at Ancaster. This is undoubtedly the same rock as that of Cave in Yorkshire, and it is continuous with the same general character as far as Grantham, between which place and Stamford there appears to be some change.
Inferior oolite sand.

Between Stamford and Peterborough the series was recorded thus: (1821:)

Cornbrash
Clay of some thickness.
Sandy laminated beds at Pilsgate.
Interval not known.
Rag beds of Barnack.
Stamford oolites, and
Inferior oolite sand.

On the line from Wandsford, through Weldon to Rockingham: (1821:)

Cornbrash very distinct.
Clay of some thickness, nothing else observed.
Weldon oolite or rag, the same as the Barnack rag.
Interval, presumed to be clay, under some breadth of Rockingham forest
Brown sand of Rockingham Hill, with interlaminated white limestones.

It might appear from these statements that the slates of Wittering and Collyweston are near the Northern end of these deposits; they are unknown at present in a distinct form North of the Welland, except at Market Deeping, though probably represented by the sandy cap of the Lincolnshire oolites.

Collyweston slate.

The slate of Collyweston is associated with beds of oolite and compact limestone, and presented to Mr Murchison and the author the following detailed section.

Local Names.	Ft.	In.	Description.
Rubble........	4	0	Imperfectly bedded oolite.
Cale	4	0	Irregular and broken beds of oolite.
Bedding sand ..	1	3	Fine yellow sand indurated at top and at bottom into concretionary and slaty layers.
Broad	4	0	Brown hard oolite graduating upwards to the sandy layers above. Thin beds, not burnt to lime.
Limestone	1	6	Hard, compact, not oolitic, containing brachyphyllum, ferns, and trigonellites.
Betch.........	1	3	Irregular sandstone.
Slate......2 to	4	0	Masses irregularly spheroidal flattened, very fissile, in general calcareous grit not at all oolitic, but shelly, with littoral and terrestrial plants.
Fine sand			Of a yellowish colour.

The slate is quarried only in Winter, for if dried by the Summer Sun and wind, it hardens and will not split. The holes are blocked up in Spring, and the quarrymen only employed in preparation of slate. It is, in general, very equally laminated. The splitting is caused by organic exuviæ.

Stonesfield slates.

The Stonesfield slates near Oxford have been almost universally esteemed of the same age as these Collyweston rocks.

At Stonesfield two beds of concretionary masses, capable of being easily (with the assistance of frost) split into slate parallel to the stratification, compose with sand and friable sandstones a group 5 or 6 feet thick, under 50 feet of alternations of laminated shelly oolite and thin blue clay. The following is Dr. Fitton's account of the section. (*Zool. Journal*, vol. iii.)

Rubbly limestone.
Clay with terebratulites.
Limestone.
Blue clay.
Oolite.
Blue clay.
} 32 feet.
"Rag," consisting of shelly oolite, with casts of bivalves and univalves.

The slate beds consisting of	"Soft stuff," 6 in. yellowish-sandy clay with thin courses of fibrous transparent gypsum. "Upper Head," 1 ft. 3 in. to 1 ft. 6 in. sand enveloping a course of spheroidal laminated calcareous grit stones which produce the slate. These are called "Potlids" from their figure, and receive with the other slaty bed the name of Pendle, as characteristic of the workable stone. The stone is partially oolitic and shelly, sometimes full of small fragmentary masses. "Manure or Race," 1 ft. slaty friable grit rock.
The slate beds consisting of	Lower Head 1 ft. 6 in. to 2 ft. sand and grit, including a course of spheroidal concretions of slate like that described above. Bottom stuff, 1 ft. sandy and calcareous grit with admixture of oolitic grains.

The floor of the slate beds is rag like the oolite above.

Most of the Stonesfield fossils, and in particular the jaws of didelphidæ, have been extracted from one or other of the courses of slate.

We may now return to the Bath series of oolites, and accompany Mr. Lonsdale in his recent survey of their extension to the Northward.

Lower oolites of Gloucestershire.

The *inferior oolite* in the South of Gloucestershire consists of nearly equal divisions of soft oolite and slightly calcareous sand; but in the Northern division of the County the latter, for the greatest part, is replaced by a yellow sandy limestone. The freestone beds, which are not to be lithologically distinguished from those of the great oolite, gradually increase in number and thickness from the neighbourhood of Bath to the Cotteswold, East of Cheltenham, where they constitute the whole of the escarpment. This vertical importance is retained through the North of the country examined; but to the Eastward of the valley, ranging from Stow on the Wold to Barrington, near Burford, a change takes place both in the structure and thickness of the formation. The freestone beds are there replaced by strata of nodular coarse oolite, containing numerous impressions of *clypeus sinuatus*, the sandy portion consists of only a thin bed, and the thickness of the whole of the inferior oolite group is diminished from 150 to about 50 feet.

The *fuller's earth* loses its importance in proceeding Northward, yet it was traced as a parting between the great oolite and the inferior oolite, as far as a line passing from the neighbourhood of Winchcomb to Burford, but to the North-East of this line it thins out.

Great oolite. The threefold arrangement of upper rags, fine freestone, and lower rags, into which this rock is naturally divided near Bath, does not prevail uniformly in our progress Northward.

The upper rags, consisting of soft freestone and hard shelly oolite, were traced to Cirencester; but to the North-East of that town they are replaced by a rubbly, white, argillaceous limestone. The beds of the middle division become chiefly a hard oolitic limestone. At Wotton under Edge the lower rags are replaced by beds of fissile, calcareous sandstone, which runs through the whole of Gloucestershire to the neighbourhood of Burford. They are extensively worked as a tile stone, possess the lithological character of the Stonesfield slate, have their fissile property in the same way developed by exposure to atmospheric agency; contain *trigonia impressa*, the characteristic fossil of Stonesfield; and on comparing the strata of Burford with those which rest at Stonesfield on the slaty beds, it was found that an almost perfect identity of character and order of position prevailed at the two localities. The Windrush quarries near Burford give the following section for comparison with that of Stonesfield previously detailed.

Top.	Rubbly limestone	1 foot.
	Brownish marlstone	6
	Rubbly limestone...............	4
	Pale sandy marl..........	3
	Rubbly limestone	½
	Light-coloured clay	½
	Rag and freestone	15
	Sandy laminated grit...........	—

Mr. Lonsdale has thus corrected the almost universal error of English Geologists in classing the Stonesfield slate with the forest marble, and has assigned its true place at the base of the great oolite; a most important alteration in every point of view.

The forest marble was found to possess the same characters as near Bath, consisting of a thick stratum of laminated shelly oolite, interposed between beds of sandy clay, containing laminæ of grit; and to have, from Bath to near Fairford, for its uppermost stratum, a deposit of loose sand, containing large masses of calcareous grit.

It is hardly to be doubted that the slate of Collyweston is coeval with that of Stonesfield, but it must be left to further investigation to decide whether the thick oolites of Lincolnshire comprise both the great and inferior oolite of Bath, or which of them exists there alone. It is now ascertained that there are calcareous slaty beds in two points of the series between the cornbrash and the inferior oolite; it is known that both the great oolite and inferior oolite are subject to great variation of lithological character and thickness, and that the fuller's earth which distinguishes these rocks at Bath is extinct, or nearly so, North of Burford. The problem, therefore, now presented to Geologists by the yet unfinished survey of the oolites, is rather complicated, and demands much labour to perform with full effect. It should be begun by taking up the subject where Mr. Lonsdale's observations end, *viz.* at Burford, and the ground examined minutely Northwards. We may venture to promise that this will not be wholly neglected.

Middle Oolite Formation.

General description.

Very strong analogies accompany all the leading divisions of the oolitic system, and mark them as the products of a succession of similar causes. As the oolites of Bath lie enclosed between strata of calcareous sand, so those of the middle division are imbedded between strata of calcareous sand and sandstone, and the association of the upper oolite with green sands at Swindon and Thame, is probably of the same intimate description. The organic fossils of all the divisions have a striking general resemblance, and the composition of the rocks is liable to similar variations.

The physical features impressed on the geography of the country which they traverse are also very similar. As the consolidated strata of the lower oolite formation form a high escarpment, which overlooks the plains of argillaceous lias; so the limestones and sandstones of this middle group rest on a bold edge, above the vales of Oxford clay, and the upper oolite rocks in the few places where they occur domineer in the same manner over the vales of Kimmeridge clay. It might have been attended with some convenience to have considered these thick clays in formations apart from the rocks, as the lias has been separated from the lower oolite, but they are from various causes so connected with them that it would have injured the practical utility of the classification.

The general characters of the surface of the middle oolite formation, are a moist valley of Oxford clay below a dry range of hills, furnishing copious springs from the calcareous grits and oolite. Dry valleys, deep wells, narrow dells, washed by the rapid streams, occur, especially in the districts of greatest altitude, and one unacquainted with the series of formations might recognise in the general aspect of ***this***, the *description* usually given of the lower oolite range. Outlines of the oolites and sandstones occasionally cover insulated hills of the subjacent clay, and prove the denudating power of ancient floods. The altitude of this range of oolite nowhere equals that of the lower oolite in the same region. Thus while in Yorkshire the rocks rise in Botton Head to 1485 feet above the sea, the former reach on Black Hambleton 1240 feet. In Oxfordshire and Gloucestershire 800 or 900 feet is the height of the lower oolite, but 400 or 500 feet that of the middle oolite.

Range and extent.

This formation is upon the whole less continuous than the one described before, yet the discontinuity is not of the whole mass, but chiefly of the group of oolites and sandstones. These have a considerable developement in Dorsetshire; first on the coast at Weymouth, and secondly from near Sturminster to beyond Wincanton, where they produce oolitic freestone. Hence to Longleat Park they are unknown. From Longleat their range is unbroken by Westbury, Calne, Wootton Basset, Highworth, Farringdon, and Abingdon, to the banks of the Thames at Oxford. They can be traced under Shotover, and towards Brill, a few miles, but their further course is unknown, till we arrive under the Wolds of Yorkshire near Acklam. At this point emerging from beneath the chalk, they encircle the Vale of Pickering by Malton, Helmsley, Pickering, and Scarborough, increase greatly in importance, and assume more completely than in any other part of England, excepting perhaps Weymouth, the full characters of their formation. But while the oolitic group is thus dismembered into four widely detached regions, the Oxford clay beneath is as remarkably connected from the North side of the Dorsetshire downs, by Wincanton, Melksham, the Vale of the Isis, Ottmoor, the Vale of Bedford, Huntingdon, the Western border of the Fens, and the Vale between the Cliff and Wold ranges of Lincolnshire to the banks of the Humber. Beyond the unconformity of the chalk wolds, its course is undivided beneath the slope of the calcareous grit round the Vale of Pickering to Scarborough.

We shall now offer a few details of the internal structure and variations of these rocks.

The *clay* below the Kelloway rock has been very little noticed, and is indeed not very important. It occasionally contains pholadomyæ and other shells near Bath, and more frequently abundance of selenite, and on the coast of Yorkshire has yielded some curious remains of crustacea. As for the greater part of the range of the Oxford clay the Kelloway rock is unknown, this clay can seldom be distinguished. In Yorkshire it barely reaches a few yards, and generally is less than three feet in thickness.

Kelloway rock.

The Kelloway rock, so named by Mr. Smith from Kelloway Bridge in Wiltshire, which is almost the only place where it occurs in the South of England, is in that County more remarkable for the beauty, peculiarity, and abundance of ammonites, gryphææ, and other organic remains which it produces, than for either its thickness or continuity. It is there a calcareous sandstone, appearing when devoid of organic remains very similar to those which accompany the coralline oolite, externally brown, internally grey or blue, of a rubbly nodular structure, altogether less than twelve feet thick. From Wiltshire to Northamptonshire no mention is made of this rock, but it was found with its usual fossils at Boziate Hill, near Wellingborough, by the writer of this Article, in company with Mr. Smith in 1820.

In 1821, the same observers established the occurrence of the Kelloway rock at Hackness and Scarborough on the sea-coast of Yorkshire. It is coextensive in that County with the range of the Oxford clay, from under which it rises into an escarpment. It arrives sometimes at a thickness of sixty feet, and is then locally distinguishable into several portions. It is, however, altogether a mass of sand and calcareous sandstone, with or without organic remains; the upper beds very thick, indurated by admixture of oxide of iron, and multitudes of gryphææ, belemnites, ammonites, and aviculæ, and other fossils. Not unfrequently in the vicinity of the shells it becomes sufficiently calcareous to assume the character of a sandy oolite, sometimes ferruginous like that of Dundry. The sandy parts of the mass are often variously stained brown, reddish, yellow, or remain perfectly white, in layers or irregular stripes, and traversed by dissepiments of oxide of iron. In a very few places it is useful as a building stone.

There is perhaps no more curious fact on record than the occurrence of this apparently indefinite rock, with almost identical characters, after so great an interruption of continuity.

Oxford clay.

The Oxford clay (clunch clay of Smith) appears, in the whole of its range South of the Humber, a pale blue clay, turning yellow on the surface, with large sparry septaria, and some layers of chocolate-coloured shale, (Tytherton,) with ammonites and other fossils. In Yorkshire, it is less tough, and more generally laminated, gradually changing in quality to the Kelloway rock below, and the calcareous grit above. Most of the organic remains which it yields belong to the lower part of the stratum, and are in general identical with or very similar to those of the Kelloway rock. Taken in general terms, the suite of fossils at Weymouth belonging to the Oxford clay is considerably allied to that of the Kelloway rock and Oxford clay of Yorkshire, but further comparison of the species of ammonites is yet needed. In the Museum at Strasburg fossils of the Kelloway rock, as well as of the Oxford clay, are recognised.

It is painful to observe the dreadful waste of money in ill-advised trials for coal along the line of the Oxford clay. The least fragment of jet or morsel of bituminous shale, especially if accompanied by "blue metal," is enough to make a credulous proprietor listen to an ignorant collier, and throw away the value of his solid land in sinking for the imaginary treasures beneath it.

Coralline oolite group. Lower calc grit, Wilts, &c.

The *lower calcareous grit* should be carefully distinguished from the iron sand, with which Mr. Smith has occasionally confounded it, nor is the distinction difficult, for, independent of its geological position, the calcareous grit is not particularly ochraceous, and never assumes that dark ferruginous aspect so remarkable in the other rock. In Wiltshire, where it was first observed, it appears as a thick stratum of sand, inclosing irregular beds of sandstone, or of calcareous grit, which assumes the aspect of coarse limestone. These sandstones are brown externally, but grey or blue within. Irregular layers of clay occur in places, and friable beds of decomposed shells. The prevailing colour of the sand is yellow, but sometimes it is ash-coloured. At Studley, near Oxford, Dr. Buckland detected a peculiar bed of clouded grey colour, and very tough and dense texture, a sort of argillaceous chert, rich in pinnæ, ammonites, and other organic remains. It probably belongs to the lower part of the rock.

The calcareous grit of Heddington, also rich in organic remains, ammonites, belemnites, plagiostomata, pectines, &c., is a very coarse rock, with an abundant admixture of quartz pebbles, chiefly of small size, and fragments of shells. It forms irregular beds and concretions in beds of quartzose sand, mixed with calcareous matter.

Professor Sedgwick's description of the calcareous grit of Weymouth makes us acquainted with a more complete series than that of Wiltshire and Oxfordshire. The following statement of beds there is in the ascending order:

a. The lowest beds upon the Oxford clay are black, and meagre to the touch, filled with irregular branching stems like alcyonia.
b. Thin beds of yellow sand and sandstone.
c. Strong ferruginous jointed beds of calcareous grit.
d. Blue argillaceous beds, alternating with hard compact beds with an even fracture.
e. Yellow sand like *b*, with beds of calcareous grit in the upper part.
Beds of oolite succeed.

The section of the lower calcareous grit on the Yorkshire coast between Filey and Scarborough has a striking resemblance to that of Weymouth. Immediately on the Oxford clay rests a series of grey marly sandstones, 70 feet thick, gradually becoming more yellow and more consolidated upwards, till they assume the harshness which belongs to stones usually called cherty. This cherty bed appears to correspond with that mentioned before at Studley. It continues across the moors to Hambleton. Above these runs a band of yellow sand, nine feet thick, enclosing large spheroidal highly indurated calcareous balls. This band is traceable through the interior, where it forms rabbit-warrens, as far as Whitestone Cliff, and there the balls are of immense size. When they fall out, the rock looks cavernous. The upper part of the rock consists of strong beds of calcareous sandstone, very remarkably covered on the surface, and also penetrated by branching cylindrical bodies, which continually remind us of sponges. The upper beds of this series are of a redder colour, and more calcareous than the others, remarkably full of shells, and in some places alternate with two or three beds of oolitic limestone also shelly. In the interior of the moors, they are often used for wallstone. It is not always quite easy to draw the line between them and the oolite above, especially when the latter is unusually shelly, and no coral bed intervenes.

According to Mr. Lonsdale there is in Wiltshire a pale blue clay, 10 feet thick, interposed between the lower calcareous grit and the coralline oolite.

The coralline oolite, or coral rag group, as described by Smith, Conybeare, and Lonsdale, near Oxford, Wootton Basset, and Bath, seems not so complete a series as that described by Professor Sedgwick at Weymouth, and by other authors in Yorkshire.

Weymouth. The thickness of the whole group is greater in Yorkshire than elsewhere, but no where in that country exceeds 80 feet. The section at Weymouth gives above the calcareous grit the four following groups:

Many beds of pure oolite with beds of argillaceous partings, alternating with other shelly oolitic beds, somewhat resembling forest marble. In some of these beds the oolitic particles are associated with a variety of marl, and are incoherent.
Thin beds of oolitic marl, containing innumerable specimens of the small clypeus clunicularis, casts of melaniæ, &c.
Beds of impure sandy oolite, containing, besides other fossils, a few specimens of ostrea deltoidea.
Thick limestone series, at the bottom of which lie masses of coral rag, containing caryophyllia annulata, astrææ, &c. with innumerable fragments of trigonia clavellata. In the higher portion are many meagre sandy beds, nearly resembling the lower calcareous grit, but more calcareous, and with a finer suite of organic remains.

shire, Wilt- Mr. Lonsdale describes the Wiltshire coral rag in three divisions which do not succeed one another in any certain order, but rather intermix with and replace one another. One of them, from which the formation takes its name, is an irregular mass of nodules mostly crystallized, but sometimes earthy, and connected together by pale bluish clay. These nodules consist of little else but corals of the genera astrææ, caryophyllia, and agaricia, especially the former, which sometimes separately compose the whole mass. The lower part of this bed sometimes affords a dark blue crystalline limestone.

Another form of the rock is found in the oolite of Calne, which consists of alternations of hard shelly oolite used for flags, and soft, perishable, scarcely oolitic, limestone, workable by sawing parallel to the beds.

This form of the rock passes into the third or rubbly oolite, which is the most abundant variety in Wiltshire. This is a nodular rock with very indistinct stratification and much irregularity of texture, occasionally with ova three-tenths of an inch in diameter, constituting what is called pisolite.

In the deep pit through Kimmeridge clay on the line of the Wilts and Bucks Canal, this rock was very thin, scarcely oolitic, but chiefly a cellular mass of caryophylliæ and astrææ, and a similar character prevails in some quarries in the neighbourhood of Wootton Basset. Below it the lower calcareous grit was in the state of loose sand.

Oxfordshire. Mr. Conybeare divides the coralline oolite near Oxford into two parts, of which the upper is a calcareous freestone of close texture, full of comminuted shells, and irregularly oolitic or pisolitic.[*] The beds are very thick, and the stone has been much used in buildings at Oxford, but is not found to be durable. The lower part is the true coral rag, consisting of two or three courses of nodular rubbly rock, very crystalline in aspect, and composed of masses of astrææ and caryophylliæ, with admixture of echinital and shelly fragments.

Yorkshire. In Yorkshire the lower beds of the coralline oolite are in general exceedingly shelly, and full of clypeus dimidiatus, clunicularis, &c. and on the North side of the Vale of Pickering, at Hackness, Ebberston, &c. are marked by an irregular bed of coral (astrææ) and sponges. The middle part of the rock is regularly bedded with thin partings of clay, and very large vertical joints; the different beds vary much in the same quarry, from a soft, loose, whitish oolite to a solid rock with blue centres and large pisolitic spherules. At Malton it is more uniformly oolitic, and very full of melaniæ, trigoniæ, plagiostomata, &c. and organic remains of all kinds. Near the upper part in the Ayton quarries is a bed of caryophylliæ and echini, and the rock is crowned at Sinnington, Helmsley, &c. by a bed filled to excess with turritellæ and melaniæ. Melania striata and turritellæ occur near the top of the rock about Brompton and Hackness, but at Malton they lie indiscriminately. Ammonites chiefly belong to the lower beds. About Kirkdale and Helmsley layers of obscurely defined nodules of bluish-grey chert, having the texture of sponges, lie in the lower part of the rock, and remind us of the silicious sponges of the Portland oolite.

These sections will show at once the general accordance of the characters of this irregular oolite, its variable thickness, and indefinite order of succession, circumstances which belong indeed more or less to all the oolitic formations. The corals which characterise the rock, lie very unequally, yet perhaps we may perceive a tendency to form two layers, one near the top, the other at the bottom of the rock. The Oxford series seems imperfect by the deficiency of the upper members; a circumstance probably connected with ancient denudations, by which also this rock has been greatly affected in different parts of Yorkshire.

Upper calc grit.

The upper calcareous grit, obscurely indicated at Weymouth, and very thin and unimportant in Wiltshire, (where it appears separated from the oolite by ferruginous clay,) is of considerable note along the North side of the Vale of Pickering, especially about Helmsley and Hackness, It then reaches even a thickness of 60 feet, and by intercalating its upper part with the Kimmeridge clay establishes a transition from the middle to the upper oolite formation. It is in general more ferruginous and less cherty than the lower calc grit, and in Yorkshire contains apparently fewer organic remains, but of the same kinds. It has been entirely removed by denudation from the oolite cliffs of the coast. At Weymouth its fossils are numerous and fine.

Upper Oolite Formation.

The upper or Portland oolite formation, consisting of limestone above and clay below, might be expected to occupy a country, whose physical geography should strongly resemble that of the district of coralline oolite. The area occupied by the calcareous group is indeed so very small in England, that little can be said on this point concerning it, Its commanding appearance in Portland Isle, in the Vale of Pewsey, at Swindon, and in the Vale of Aylesbury, is analogous to that of the oolitic rocks in general, and the sands with which it is in some places associated, increase this resemblance.

Kimmeridge clay.

The Kimmeridge clay in its much longer and more connected range in Dorsetshire, Wiltshire, Berkshire, and Buckinghamshire, (where it can be traced at least as far as Little Brickhill,) and beneath the wolds of Lincolnshire, and through the Vale of Pickering in Yorkshire, presents the usual characters of a thick clay deposit, broad vales with a cold, stiff soil, without springs.

The Kimmeridge clay at its typical locality in the Isle of Purbeck appears in the cliffs, as a laminated clay, bluish or greyish-yellow, dividing spontaneously like other shales into large tabular masses, the joints often lined by calcareous spar. Layers of small argillaceous nodules occur. It passes gradually into a bituminous shale, imperfectly combustible, and finally into layers of brown shaly coal, specific gravity 1.319, which burns with a smoky yellowish flame. Alum was formerly manufactured from these shales. The group is supposed to equal 600 feet in thickness. (*Geology of England*) In the Vale of White Horse at Even Swindon, it was penetrated by a well to the depth of 233 feet, and the additional thickness of the incumbent beds in Swindon Hill being taken at only 70 feet, the stratum will appear 300 feet thick. Near Oxford it is only 100, and at Bagley Wood was found only 70. In Lincolnshire and Yorkshire its thickness generally appears much less through the unconformity of the chalk strata.

Near the bottom of the Kimmeridge clay in the Vale of White Horse, below the layers of ostrea delta, were found a band of coarse oolitic ironstone with fossils and layers of septaria, with ammonites, trochi, and many other fossils much allied to those of the coralline oolite. Shale and bituminized wood were found at about the middle of the clay, and above this a course of thin balls of stone with mineral water. Near Weymouth the lower part of the clay contains, *above* large beds of ostrea delta, beds of ferruginous impure calcareous grit, partially oolitic, and alternating with beds of red and green sand and blue clay containing ostrea delta. Small bands of calcareous grit may be seen in the lower part of the Kimmeridge clay of Yorkshire, below layers of ostrea delta. It thus appears that the remarkable species of oyster so named by Mr. Sowerby is a very characteristic fossil of the lower parts of this clay group, and its manner of occurrence is equally so. For whether in Yorkshire, at Helmsley, Kirby Moorside, Elloughton, &c. in Lincolnshire at Market Rasin, at Little Brickhill in Buckinghamshire, at Heddington near Oxford, at Even Swindon and Pewsey Vale in Wilts, or at Weymouth, and we may add, at Havre, it always appears in broad continuous floors, parallel to the planes of stratification, the valves usually together, with young ones occasionally adherent to them, and entirely imbedded in clay, without nodules or stones of any kind, and without any other organic remains in the layers.

Portland oolite, &c.

The upper oolite group consists, like those previously described, of a variable mass of sand and sandstone concretions, surmounted by a partially oolitic, shelly limestone. Were the rock to be seen more completely it is probable that it would also show a less definite arenaceous zone above. In Purbeck it is covered by the fresh-water or Wealden formation, and in Wiltshire, Berkshire, and Buckinghamshire by the green sand.

The varieties of composition in the limestone are such as have been noticed for the other oolites, *viz.* fine-grained white oolite, loose granular limestone of earthy aspect, and compact cretaceous limestone with conchoidal fracture.

In the Island of Portland the groups present, according to Mr. Webster, (*Geological Transactions*,) the following characters.

Upper beds ..	*Stone brash*, a cream-coloured limestone	3 feet.
	Parting of the same with black clay ...	1
	Cap stone, in three layers, with partings of clay, cream-coloured and hard, so as to turn the points of the tools.....	10
Middle beds ..	*Roach*, a rock composed of fragments of oyster shells, cemented together	6
	White beds, marketable stone	5
	Layers of flint and stony rubbish......	6
	Middle bed, marketable stone, with few marine impressions	5
	Parting stone with shells of no value ..	2
	Third bed with few shells, generally the most saleable freestone	7 to 14
Lower beds ..	Many layers of flints and of unserviceable stone......................	50 to 60

Still lower, according to Dr. Buckland and Mr. De la Beche, is a bed of sand and sandstone 80 feet thick, with green grains, and very like to the lower green sand.

At Chicksgrove, in the Vale of Tisbury, Wilts, the series of limestones, more or less associated with sand, especially in the lower part, reaches more than 60 feet in thickness. Miss Benett, who has extracted so many treasures from those quarries, has given a minute section of the beds.

The five upper beds, amounting to 29 feet, consist of white limestone, locally called chalk, with one interposed layer of bad shelly stone, and a band of cherty flint 4 inches thick. The middle bed of this limestone, 2 feet thick, is excessively rich in shells, but the thicker beds above and below contain none.

The next three beds of the quarry, amounting to 10 feet, consist of sandy limestones, with fragments of shells.

Five beds below consist of sandy limestone, mostly compact and shelly, with grains of green sand in greater or less abundance.

The three lowest beds are composed of loose sandy limestone, with more or less of the green grains before noticed, shells and fragments of shells.

The shells most abundant at Chicksgrove are trigoniæ, pectines, ammonites, uniones, trochi, &c.

Brill, &c.

The imperfect sections at Brill Hill and Garsington present several points of analogy with the above section, especially in the presence of the cretaceous bed, and the quantity of sand below the calcareous part of the rock is well seen here and at Shotover, where it encloses in the lower part large, grotesque, concretionary blocks of sandstone, sometimes full of shells, and generally abundant in green grains.

Abundance of green grains accompany these lower beds in their course through the Vale of Aylesbury, and are also recognised at Swindon.

The height of the ground occupied by the detached portions of the upper oolite group is considerable in Brill Hill, (780 feet,) in Shotover amounts to 500 feet, at Swindon probably 400 feet, in Portland 300 feet, but in the Vale of Pewsey it is very low.

Dirt bed of Portland.

One of the most interesting observations concerning the circumstances which intervened between the marine deposits of oolite and the fresh-water or estuary deposits of the Purbeck clays and limestones, is that of Dr. Buckland and Mr. De la Beche on the *dirt bed* which lies between these groups of strata in the Isle of Portland. This bed is compared by those acute Geologists to black vegetable mould. The stems of cycadeæ and larger coniferæ, which are found in this bed, often "stand erect, and have their roots attached to the black soil in which they grow;" thus presenting us with an ancient submerged forest, for comparison with the more modern submarine forests which in so many points margin the English, Welsh, Scotch, and Irish coasts.

It is concluded by these authors that the Portland rock, whereon these plants are stated to be in the place and attitude of growth, had been raised to become dry land, and then sunk again, under such circumstances as to become covered by fresh water, which produced the Purbeck limestones and clays; and it appears a matter of probable inference that at the same periods the whole Wealden district was submerged under nearly the same circumstances. The absence of conglomerates and dislocations appears to prove that these submersions were effected quietly and gradually; certain beds of oysters show that the waters were at least occasionally brackish, the sea again regained its dominion, and deposited the cretaceous rocks and marine testacea, and finally yielded place again to a lacustrine deposit.

Wealden Formation.

Until the appearance of Mr. Mantell's Works on the Geology of Sussex, the peculiar relations of the vast thickness of sandstones and clays of the interior of Kent, Sussex, and Hampshire, were entirely misunderstood. No one supposed that these immense strata were altogether of a peculiar type, and interpolated amidst the rest of the marine formations, as a local estuary formation, of which only very faint traces can be perceived in other parts of England. Always striving to make particular results harmonize into one general system, Mr. Smith and other Geologists at one time referred the interior sandstones to the "iron sand," and the Weald clay to one of two beds, confused under the title of oak-tree clays. This mode of classification seemed, indeed, tolerably consistent with the mineralogical characters of the formations, but was found wholly at variance with their animal and vegetable remains. For these, instead of being fossils of the iron sand and Kimmeridge clay or Gault, were really a peculiar suite of terrestrial and fluviatile exuviæ of which very few traces have been perceived elsewhere.

Mr. Mantell's publications have clearly shown that the true place of the whole Wealden formation is *below* the iron sand or lower green sand, and, probably, immediately *above* the Purbeck limestones, which overlie the Portland oolite.

The only places in England where analogous beds are known to occur, are at the back of the Isle of Wight, in the Isle of Purbeck, along the South side of the Dorset Downs, and in the Vale of Tisbury in Wilts.

Groups of the Wealden formation.

The Wealden formation naturally divides itself into two groups, which give distinct physical features to the Countries which they occupy; and if to these we add the Purbeck limestones below, we have the following order of succession.

Upper group. Weald clay.	Pale blue clay, of considerable but variable thickness, having in the upper part septaria of argillaceous ironstone, and in the lower part beds of the shelly limestone, called Sussex marble.
Middle group. Hastings sands.	Fawn-coloured sand and friable sandstone. (Horsham beds.) Calciferous sandstones, alternating with friable and conglomerate grits, resting on blue clay. (Tilgate beds.) White sand and friable sandstone, alternating with clay. (South sandstone.) Bluish-grey limestone alternating with blue clay and sandstone shale, and some beds of calciferous sandstone. (Ashburnham beds.)
Lower group.	The Purbeck beds, consisting of shelly limestones alternating with clay.

Weald clay.

The Weald clay forms one general valley, most conspicuous on the Northern side, between the elevated central ridges of the Hastings sands, and the chalk downs of Kent, Surrey, Hampshire, and Sussex, from Hythe by Tunbridge, Hartingcombe, Hailsham, to Pevensey.

Hastings sands.

The Hastings sands distinguish themselves by forming a central axis of elevation along what is called the Forest ridge, by Battle, Crowborough, and Tilgate Forest to Horsham: Crowborough, the highest point, is 804 feet above the sea. This arrangement may be studied on Mr. Mantell's and Mr. Smith's sections, but the general axis of elevation is so confused by a number of local disturbances, and is, moreover, so broad a ridge, that its character is often overlooked. Those who suppose the chalk of the Northern and Southern escarpments to have once extended over all the area of the Wealden formation, and to have been subsequently removed by watery violence, have rightly applied to this devastated region, the name of the great denudation.

Whether, in truth, the Purbeck beds should be thus ranked in a separate section, or be considered as the equivalent of the whole argillo-calcareous formation of the Weald, is, perhaps, matter of doubt. It is, however, certain that the most decided analogy prevails between the upper part of the Purbeck series and the marble beds of the Weald clay. We shall now add a few details on these groups in succession, beginning with the Purbeck beds.

Purbeck beds.

These consist of many thin strata of argillaceous limestone, alternating with slaty marls, and form an aggregate of 300 feet in thickness. Mr. Webster describes the beds of stone as consisting chiefly of shells, usually, but without certainty, referred to the fresh-water genus paludina. They might, with equal confidence, perhaps, be supposed to belong to an ancient littoral genus of the family turbinacea. But a small portion of these calcareous beds is fit for columns, chimney-pieces, and other architectural uses for which the "Purbeck marble" is celebrated. Our cathedrals were formerly supplied from quarries in the very highest part of the series, which are now extinct. The shells in this stone are usually *small* paludiniform shells. According to Mr. Middleton, three *veins* of good stone, not exceeding altogether 17 feet, lie in the midst of alternations of other stone compact or shelly, and black slaty clay, more than 270 feet thick.

Ashburnham beds

The Ashburnham beds, above 100 feet thick, consist of shelly limestone and shale, alternating with blue clay, and containing subordinate beds of ironstone and sandstone. Limestone, of a dark bluish-grey colour, full of immense quantities of bivalve shells, more or less spathose, is the most characteristic deposit of the group. The shale which is associated with this limestone, sometimes contains the same shells in a white friable state. In ancient times the rich ironstone accompanying this limestone was, through the use of the latter as a flux, converted into iron by wood fires, and thus, in part, have the vast forests of Sussex been diminished. The shells are usually supposed to belong to cyrena or cyclas, in accordance with the opinion that the whole Wealden formation is of fluviatile or estuary origin; but this is still an obscure point, and some of the shells appear to resemble nucula. At Poundsford a bed of calciferous Tilgate sandstone is found *under* a bed of the Ashburnham limestone, and the same was found in some of the limestone pits of Lord Ashburnham.

Worth sands.

The Worth sands and sandstones afford a fine soft building-stone, extensively dug at Worth, near Crawley. The sandstone is for the most part of a white or pale fawn or yellow colour, and occasionally contains leaves and stems of ferns, arundinaceous plants, and other vegetable reliquiæ. They may be well studied in the cliffs near Hastings.

Tilgate beds.

The Tilgate beds consist of three divisions. The lower one is clay or marl, of a bluish-grey colour, alternating with sand, sandstone, and shale, and containing stems of vegetables, and very rarely bones and shells.

The middle division consists principally of large concretional or lenticular masses of a compact calciferous grit, or sandstone lying in sand. The stone is fine grained, of a light grey colour, inclining to blue or green, and is composed of sand, cemented together by about 25 per cent. of crystallized carbonate of lime. Its fractures frequently show glistening faces. The lower portions of this bed form a conglomerate, and contain *pebbles* of quartz and jasper, sometimes *evidently* water-worn. (Of this stone are three or four layers, from 2 or 3 inches to 1½ or 2 feet, associated with sand.) The surface of the blocks is often covered with mammillary concretions. These are the strata from which Mr. Mantell has drawn the astonishing profusion of animal and vegetable remains. The vegetables are wholly of terrestrial origin, mostly of cryptogamous and gymnospermous structure. There are probably no zoophytic remains. The testacea (mostly casts) much resemble the lacustrine genera, paludina, unio, cyrena. Fish-teeth and scales abound, with remains of a land tortoise, a fresh-water and a marine turtle, plesiosaurus, crocodile, megalosaurus, hylæosaurus, iguanodon, and some kinds of aquatic birds.

Irregular alternations of sand and sandstone, of various shades of green, yellow, and ferruginous, the surface often furrowed like the sand on the sea-shore, cover the whole group.

The Horsham beds of sand and friable sandstone, grey, yellow, or ferruginous, with occasional interspersions of ironstone, and a very large proportion of disseminated small linear portions of lignite, form the upper division of the Hastings group, and encircle the immense Tilgate beds. The sandstone is micaceous and ferruginous, and sometimes holds a considerable proportion of calcareous matter. These beds alternate with a stiff grey loam or marl. The lignite is conjectured to have been derived from carbonized ferns.

Weald clay group.

The Weald clay group, besides its general physical features already mentioned, has little to detain us. The septaria of this clay are composed of a deep red, argillaceous ironstone, and with remains of fishes and cyprides, occur in layers of two or three feet in thickness in the upper divisions of the clay. The shelly limestones, so well known by the name of Sussex marble, appear to occupy chiefly the middle beds of the Weald clay. They occur in layers of a few inches or a foot in thickness, separated from each other by seams of clay or coarse friable limestone. The compact varieties, when polished, exhibit sections of the enclosed shells. These are usually referred to paludina, and have been compared to the recent paludina vivipara, and they are associated with the shelly remains of a minute branchiopode, (cypris?) from which circumstance it is inferred that the Weald clay is a lacustrine deposit. This shelly marble occurs all along the line of the Weald clay from Leighton to Petworth, Newdigate, South of Tilvester hill, and Bethersden in Kent: potamida? and cyrenæ have been collected from this clay.

Of fresh-water origin.

The evidence upon which it is now very generally admitted that the Wealden formation was a fresh-water or estuary deposit, is founded upon a contemplation of the organic remains, and this subject admits of three general observations.

First. There is in all the strata of the Wealden formation, whether sandy, argillaceous, or calcareous, an almost entire absence of decided marine genera of shells and zoophyta. In particular, the numerous and characteristic tribes of ammonites and belemnites, of trigoniæ, terebratulæ, and ostreæ, of echinida, stellerida, and polyparia, are entirely absent, a circumstance certainly unparalleled in any section of equal variety among marine strata.

Secondly. What shells there are have most generally the forms of fresh-water or littoral genera, and it may be remarked especially that this kind of evidence bears with most force upon the middle group.

Thirdly. The plants which abound in this middle group are of terrestrial, or marshy, and not of marine origin, and the saurian remains also indicate the littoral or marshy life of those monstrous animals.

We may therefore confidently adopt Mr. Mantell's conclusion of the fresh-water origin of the materials of the Tilgate beds, and suppose these materials to have been deposited in an estuary by one or many rivers; and also refer to a similar *place of deposit*, the lower bed of limestone and clay, and the upper group or Weald clay; but that the *materials* of these argillo-calcareous deposits were also derived from the land is not yet *proved* in the same manner as has been done for the arenaceo-calcareous deposits of the forest ridge. Whatever may have been the causes, it is probable that the change from the *truly marine* Portland oolite to the supposed *lacustrine* Purbeck beds is *gradual*, and the same must be said of the change from the Weald clay to the lower green sand. The varying force with which the water-floods of the land were introduced into the supposed estuary or gulf, may, perhaps, explain both gradations of the extreme groups and the determined fresh-water origin of the middle group of the Wealden formation.

Oolitic System.—Foreign Localities.

Range and extent.

The oolitic system is so largely developed in England as to form a very conspicuous if not the principal feature in its Physical Geography, and its extreme ramifications reach the Northern and Western coasts of Scotland, and the Eastern shore of Ireland. But the range of these rocks is still more extensive on the Continent of Europe, and obscure indications of the continuation of the lower formation of lias occur in North America and are repeated in India. In France, a broad belt of oolitic rocks borders on the East the primary rocks of Brittany and La Vendée, and sweeps round the basin of Paris from the coast of Normandy, (Calvados,) by Falaise, Alençon, Lemans, Saumur, Poitiers, Chateauroux, and Nevers, and through Burgundy, Franche-Comté, and Lorraine, till, along a line from Avesnes to Luxemburg, it abuts against the slate mountains of the Ardennes. From Poitiers the oolites continue themselves Westward to La Rochelle, Southward to Angoulême, Perigueux, Cahors, and the vicinity of Montauban. A little discontinuity here occurs, but the oolites of Rhodez and the Cevennes mountains, by continuing themselves South-Westward to Montpellier, Carcassone, and Foix, along the Northern slope of the Pyrenees to Fontarabia, and North-Eastward to Montelimart and Grenoble, and so to the Jura, and South-Eastward to Marseilles and Nice, unite into one irregular mass the whole area of the French oolite. These formations are largely developed in Spain, and, in particular, form a band on the slope of the Pyrenees.

Along the Swiss border of France runs the long calcareous chain of the Jura, and this whole mountain region is a mass of the oolitic rocks. It is therefore generally assumed on the Continent as a type of the system, and the terms Jura-kalk, Jura formation, are exactly equivalent to our oolitic system. This is connected below the alluvial valley of the Saone with the oolites of Burgundy. In its continuation Northward, the Jura ranges pass in a broad belt through Würtemberg, Bavaria, and Franconia, and reach the Maine as it issues from the Bohemian mountains.

The Jura is also connected, by crossing the Rhone below Geneva, with the limestone which follows the range of the Western Alps from Provence through the Tarentaise and Savoy into the Valais, and continues along the Oberland mountains, across the Lakes of Thun, Brientz, Lucerne, and Wallenstadt, and then beneath the Tyrolese and Styrian Alps, by Inspruck and Salzburg, to the neighbourhood of Vienna. Nor is this the end of the enormous range, for the Northern border of the Carpathians about Cracow and Dynow is defined by vast breadths of compact oolite.

On the Southern side of the Alps, the same limestones appear in great force, and stretch through Illyria and Carniola to Trent, and the Lakes Guarda, Iseo, Como, Lugano, and Maggiore.

Besides these immense ranges of rocks of the oolitic area, many smaller detached portions may be seen upon Von Buch's and other Maps, and one in the Northern part of France, around Boulogne, is of particular interest.

It appears, then, that the sea which deposited the oolites floated round, or perhaps covered the spaces where now rise on high the Alps, the Carpathians, the Pyrenees, Auvergne, the Vosges, the Black Forest, and Bohemian mountains, in general corresponding to the basin in which the saliferous system was formed. The original arrangement of the rocks has been in places immensely disturbed, and vast regions have been devastated by floods, yet no doubt the general geographical outlines of the system are nearly what they always were. It may not be easy always, in the present state of knowledge concerning the extent of subterranean movements, to say what were the depths and the shallows of this great ocean; but even toward this very considerable approximations may be made by comparing the mineral and zoological and botanical characters of the deposits in different places.

Divisions of the system.

Notwithstanding their vast extent, it does not appear that the continental oolites are any where subject to greater variation and composition than the English series.

In the North of France most of the groups acknowledged by the English Geologists may be recognised, as the lias, inferior oolite, Bath oolite, forest marble, Oxford clay, coralline oolite, Kimmeridge clay, and even the Portland oolite, (De la Beche, *Geol. Trans.*) and the organic remains are either very similar or identical. But in the vicinity of the granites of Auvergne, it is difficult to distinguish more than the lias, and one great overlying mass of oolites indistinctly divided, except by having in the lower part a ferruginous bed sometimes accompanied by ferruginous sand probably corresponding to that of the inferior oolite.

The Jura shows us distinctly the lias, and a mass of calcareous rocks, sometimes perfectly oolitic, in other places earthy or compact, occasionally interlaminated with clays, but hardly capable of any clear and satisfactory divisions. The lower parts are often ferruginous and sandy, and clearly represent the inferior oolite. The upper parts, nevertheless, by admixture of *chloritic* grains and beds of green sand, appear to represent the upper oolite series of England, until, as may be particularly observed in the Salêve, it is difficult not to allow that the oolitic and cretaceous systems are united in the cap beds of the Jura-kalk. This should be compared with the previous notices of green sand below the Portland oolite. The fucoid grits along the line of the Eastern Alps clearly belong to the green sand, and the relations of the hippurite limestone, which is at the top of the alpine kalkstein shows that the causes which in England and the North of France have occasioned *such decided* differences in the oolitic series, and established so many groups, did not obtain in these parts. It is extremely probable that this is merely the difference between littoral and pelagian deposits. In England, generally, the disturbance of a shore is indicated by the more numerous alternations, beds of clay and sandstone, rolled shells, ripple marks, and land plants, and, where these characters go to extreme, the whole formations appear changed to a coal system. Something like this happens, as before mentioned, at the Porta Westphalica, but the greater part of the oolitic limestone of France, Germany, and the Alps, appears to have been deposited in deeper and more quiet waters. Through all these Countries the *proportion* of limestone to the more mechanical deposits is much greater than the average of the English series, the marks of disturbance are mostly wanting, the lines of division are obliterated, and the products of the land infrequent. Perhaps we may in this way account for the smaller number of organic remains belonging to the Alpine limestones; for if these were eminently pelagian, they should probably contain fewer marine exuviæ, since we have good reason to believe that the deepest parts of the sea, where light can hardly penetrate, and all is dull repose, are almost devoid of organic life. As the borders of a Desert are rich in every vegetable hue and resonant with all the voices of animals, so are the borders of the sea prolific of existence, but the Sahara and the Ocean are equally dead at their centre.

The oolitic texture seems to lose itself in the same manner toward the Alps, amongst which it can be seldom seen, and in general the paucity of organic remains is greatest in the most compact or most crystalline of the varieties of these limestones. The Jura, through its whole range in Würtemberg and Bavaria, uniformly shows upon the lias a cap of rocks associated with sand, and often passing upwards into ferruginous oolite, and the same thing happens above the lias of Hanover and Westphalia.

Solenhofen beds.

In the centre of the German Jura, at Solenhofen and Eichstadt, occur beds of white fissile limestone, now universally employed in lithography, which abound in organic remains, and have been long supposed to be much related to the Stonesfield slates. This relation is, perhaps, not supported by their Geological position, for this is certainly above not only the inferior oolite previously described, but also above a considerable thickness of Jura-kalk, and a variable mass of dolomite. M. Von Dechin appears to think these beds of an anomalous character, as indeed their organic remains testify. The whole of this slaty group is seen to thin out near the mouth of the Altmühl between masses of dolomite, being entirely surmounted by green sand and cretaceous deposits. (Murchison, *Geol. Proceedings.*) The author just quoted inclines to the opinion that the higher members of the oolitic groups of England, have not yet been satisfactorily defined in any part of central Germany. This subject will be soon cleared up by the active and intelligent Geologists of Germany.

Disturbances of the Oolitic System.

The parallelism of beds over large regions, the repetitions of similar rocks at frequent intervals, and the gradual change of the species of organic remains through the whole series, appear to indicate that the long period when the oolitic system was deposited was one in which the ordinary operations of Nature were uninterrupted by paroxysms of igneous violence. On viewing the whole series of these strata, and considering the manner in which their outcrops follow one another, it appears that only a very few instances can be pointed out where any beds of the oolitic system are really unconformed to others of the same system below them. Apparent exceptions to this law are indeed presented by every detailed Geological Map, particularly in the case of the coralline oolite, but this rock appears to have been an irregular and limited deposit. It is, perhaps, hardly enough to justify the term unconformity, to show that some of the upper beds of this system have probably been removed by wasting effects of water before the deposit of the incumbent clay, as at Heddington. One case, however, may be mentioned, at Cave, in Yorkshire, where, amidst the more striking phenomena of unconformity between the oolitic system and the chalk, there appears reason to believe that the deficiency in cornbrash and forest marble systems may be ascribed to a local unconformity of the stratification of the Kelloway rock. Other instances will no doubt be discovered, but they will probably be found equally unimportant.

The case, however, is entirely different when we transport ourselves to the period immediately following the deposit of the oolites. Through a large part of England the line of the outcrop of the chalk, green sand, &c. follows pretty exactly the range of the oolitic system, and of course we must infer that for all those districts the bed and boundary of the sea were not at all changed in position in the interval between the two systems of strata. But at either extremity of the range the plane of the cretaceous system is carried over the edges of the oolites from the upper to the lower part of the system, so that at Bishop Wilton, in Yorkshire, it rests within 25 feet of the top of the red marl.

In Dorsetshire, the chalk and green sand by over extension rest on all the members of the oolite in succession, and at length, in Haldon, actually touch the red marl.

Mr. Murchison, from his interesting observations on the Ord of Caithness, inferred that this granitic mass had been upheaved in a *solid form*, and thus that the contiguous or neighbouring oolitic strata were broken up. The brecciated character so frequent in these limestones is referred to a subsequent recomposition of the fragmented parts. Without dwelling on other cases in the British dominions, we may fairly infer from this important observation, coupled with the former cases, that there was an extensive disturbance and angular movement in the interior of the Earth beneath the Sea in which the oolites had been deposited. Considerable faults, ranging East and West, accompany the elevation of the oolites in Yorkshire.

On the Continent very extensive disturbances, happening at the same era, show that this was indeed a period when the convulsive energies of the subterranean regions were strongly and extensively exerted.

To this period M. Elie de Beaumont refers a very extensive line of dislocations, connected with the elevation of Mont Pilat near Lyons, the Côte d'Or, and the Erzgebirge. It is observed that all these axes of elevation range North-Eastward and South-Westward, and in the regions intermediate between these, marking ridges and lines of undulated stratification may be traced in the same North-Eastern and South-Western direction, particularly on the broad belt of the Jura.

Without insisting upon the exact parallelism ascribed by M. de Beaumont to these lines of disturbance, we are warranted in admitting that to the convulsions at this period, the long range of oolites connected with the ridges of the Jura both in France and Germany, and with the line of the Erzgebirge, owe, if not their actual height above the sea, some of their peculiar physical features. The cretaceous system in the vicinity of these lines of disturbance appears to be unaffected by them, except by the new outlines which were then given to the embosoming ocean, from which at a later period the chalk, green sand, &c. were deposited.

The oolites which pass North-Westward from Lorraine are probably continuous under the whole of the chalky plains of Picardy, but their superficial outcrop is extinguished by the overextension of the chalk to contact with the slates of the Ardennes, nor is it renewed on the Northern side of those mountains. Yet this case may not happen through any unconformity, but be a consequence of the irregular bed of the ancient sea. Thus, the red sandstone may be covered and concealed by the oolite, and the latter may be hidden below the chalk, and yet there may be no unconformity. This view is supported by the successive coming out in proceeding to the South-East from Avesnes, first of the oolite, then of the keuper, muschelkalk, and red sandstone, from their abutments against the older slates.

Table of Organic Remains in the Oolitic System.

N. B. The different oolitic formations are designated, where known with certainty, by the letters *l*, *m*, and *u*, (lower, middle, upper,) attached to the several localities.

	Calamites Nilsoni			Ditto.	
Of uncertain tribes	Mammillaria Desnoyersii				Mamers, *l.*

The Valorsine and Tarentaise slaty rocks, supposed by Elie de Beaumont to be of the age of lias, contain plants of the carboniferous epoch. If the Geological situation of these rocks be rightly determined, we must conclude that certain tribes of plants which flourished in the carboniferous epoch, existed in the vicinity of this deposit, under some peculiar circumstances, through the whole of the new red sandstone period, and were finally extinguished at the commencement of the oolitic era. These plants are in a singular state of conservation, the vegetable substances being replaced by talc—perhaps an effect of the igneous agency exerted in elevating the Alps, which is most remarkably exhibited in the granite veins and interposed masses of the Valorsine. The lias along the Alpine chain is frequently prismatized and converted into a kind of slate.

POLYPARIA.

N. B. The lias contains very few traces of Polyparia. Anthophyllum sessile is described by Goldfuss from "the upper part of the lias," Thurnau.

Family.	Name.	Upper Jura limestone of Wurtemberg, Bavaria, Swisserland, &c.
Fibrosa	Achilleum dubium	Solenhofen.

ANNULOSA.

Name.	Lias.	Lower Oolite.	Middle Oolite.
Vermicularia concinna, Phil.		Yorkshire coast.	
compressa, Y. and B. ovata			Scarborough.
nodus		Westow, Yorkshire.	
Serpula capitata, Phil.	R. Hood's Bay, Yorkshire.		
deplexa, Bean.		Yorkshire coast.	
squamosa, Phil.			Ditto.
intestinalis			Ditto.
quadrata		Scarborough, Bath.	
lacerata, Phil.			Ditto.
triangulata		Bradford, Wilts.	
tetragona		Ditto, ditto.	
runcinata			Shotover, Oxon.

N. B. Goldfuss (*Petrefactenkunde*) has figured and described forty-two species of serpula from the oolitic system of Germany and France. According to Von Dechen their Geological relations are as under:—

From the Lias.

Serpula tricristata, Goldf.	Banz.
quinquecristata, Mün.	Ditto.
circinalis, Mün.	Ditto.
quinquesulcata, Mün.	Baireuth.
complanata	Ditto.

From the Lower Oolites.

limax, G.	Baireuth.
lituiformis, Mün.	Ditto.
capitata, G.	Streitberg.
limata, Mün.	Ditto.
plicatilis, Mün.	Græfenberg.
spirolinites, Mün.	Streitberg.
tricarinata, G.	Rabenstein.
pentagona, G.	Streitberg.
quadrilatera, G.	Rabenstein.
quadristriata, G.	Birrach. (Burgundy.)
canaliculata, Mün.	Streitberg.
volubilis, Mün.	Rabenstein.
cingulata, Mün.	Streitberg.
substriata, Mün.	Rabenstein.
flaccida, G.	Rabenstein, Alsace.
Serpula filaria, G.	Græfenberg
socialis, G.	Bavaria, Swabia.

From the Upper Oolites.

grandis	Heidenheim, (also in lower oolites.)
conformis, G.	Buxweiler.
delphinula, G.	Streitberg, Thurnau.
gibbosa, G.	Muggendorf.
nodulosa, G.	Streitberg.
quinquangularis, G.	Normandy.
prolifera, G.	Streitberg.
planorbiformis, M.	Ditto, Thurnau.
trochleata, M.	Streitberg.
macrocephala, M.	Thurnau.
heliciformis, G.	Neufchatel, Haute Rive.
quadristriata, G.	Amberg.
convoluta, M.	Streitberg, Baireuth, &c.
Deshayesii, M.	Streitberg.
spiralis, M.	Muggend. Nutth. Heidenh.
flagellum, M.	Streitberg.
gordialis, Schl.	Nutth. Heidenh. Buxweiler.
intercepta, G.	Streitberg, Culmbach.
ilium, G.	Streitberg, Thurnau.

CRUSTACEA.

Name	Lias.	Lower Oolite.	Middle Oolite
Astacus longimanus Kœnig.	Lyme.		
rostratus, Phil.		Scarborough.	Scarborough, Malton
mitis, Phil. M S.		Ditto.	
scabrosus, Phil. MS.			Malton.
New genus? ——— Phil. MS.			Scarborough.
Cancer			Malton.

The following are from Solenhofen:—

Astacus spinimanus, Germ.
leptodactylus, Germ.
modestiformis, Holl.
minutus, Holl.
fuciformis, Holl.
Pagurus mysticus, Germ.
Scyllarus dubius, Holl.
Eryon Cuvieri, Desm.

Eryon Schlottheimii, Holl.
acutus, Germ.
muticus, Germ.
spinimanus, Germ.
Mecochyrus locusta.
Palæmon spinipes, Dem.
squillarius, Dem.
Walchii, Holl.

INSECTS.

Traces of Insects occur at Stonesfield, and very fine specimens of libellulidæ and hymenoptera at Solenhofen.

Reptilia.

This list is principally taken from Von Meyer's *Palæologica* and De la Beche's *Manual.*

Family of Saurians.	
Pterodactylus macronyx, Buckl.	In lias, Lyme Regis.
longirostris, Cuv.	In slaty limestone, Eichstadt.
brevirostris, Cuv.	Ditto, ditto.
grandis, Cuv.	Ditto, Solenhofen.
Bucklandi, Von Meyer	Lower oolite, Stonesfield.
crassirostris, Goldf.	In slaty limestone, Solenhofen.
medius, Mün.	In oolite, Manheim.
Munsteri, Goldf.	Ditto.
Crocodilus cylindrirostris, Cuv.	In lias, Altdorf.
priscus, Soëm.	In oolite, Manheim.
Altdorfensis, Cuv.	In lias, Altdorf; in Kimmeridge clay, Honfleur, Havre.
Geoffroyi, Von Meyer	In Kimmeridge clay, Honfleur, Havre.
Of Mans, Cuv.	In oolite ?
undetermined species	In lias of Yorkshire, Lyme Regis: in cornbrash, Northamptonshire, Stonesfield slate, and coralline oolite of Yorkshire.
Teleosaurus Cadomensis, G. St. H.	In oolite, Caen.
Geosaurus Bollensis, Jæg.	In lias, Boll.
Soëmmeringii	In slaty limestone, Solenhofen.
Megalosaurus Bucklandi	In Stonesfield slate.
———	In oolite, Normandy.
Lacerta Neptunia, Goldf.	Manheim.
Iguanodon Mantelli, Von Meyer	In the Wealden formation, Tilgate.
Hylæosaurus ———, Mantell	Ditto, ditto.
Pleurosaurus, Goldf., Von Meyer	In slaty limestone, Solenhofen.
Rhacheosaurus gracilis, Von Meyer	Ditto, ditto.
Family Enaliosauri, Conyb.	
Ichthyosaurus communis, De la B. and C.	In lias, Lyme, Yorkshire, Boll, &c.
tenuirostris, De la B. and C.	Ditto, ditto.
platyodon, De la B. and C.	Ditto, Lyme, Boll.
intermedius, De la B. and C.	Ditto, ditto.
grandipes, Sharpe	In lias.
coniformis, Haslan	Ditto, Bath.
other species	In the lias and Kimmeridge clay.
Plesiosaurus dolichodeirus, Conyb.	In lias, Dorsetshire, &c.
recentior, Conyb.	In Kimmeridge clay, England, Normandy.
carinatus, Conyb.	In oolite, Boulogne.
pentagonus, Cuv.	Ditto, Ballow, Chaufour.
trigonus ? Cuv.	Ditto, Calvados.
macrocephalus, Conyb.	In lias, Lyme Regis.
new species, Hawkins	Ditto, Somersetshire.
Family Chelonia.	
Emys, Mantell	In the Wealden, Sussex, Jura, Solenhofen.
Chelonia of Glaris, Cuv.	In lias, Plattenburg in Glaris.
others	Stonesfield, Sussex, Solenhofen.

Mammalia.

Didelphis Bucklandi, Broderip	In Stonesfield slate. Four specimens of the lower jaw exist. They are in the cabinets of Dr. Buckland, Mr. W. J. Broderip, M. C. Prevost, and the Yorkshire Philosophical Society. The latter specimen was obtained from Stonesfield by Mr. Platt, and by him transferred to Sir Christopher Sykes, Bart., in whose collection, now the property of the Rev. C. Sykes, it was discovered by the writer of these pages.

Pisces.

Name.	British Localities.		Foreign Localities.

Undescribed fishes	Barrow, Whitby	Portland, *u.* &c.		

The following are from the metamorphic lias of Glarus formerly called greywacke slate.

Zeus Regleysianus, Bl.
platissa, Bl.
spinosus, Bl.
Palæorhynchum Glarisianum.
Clupea Scheuchzeri, Bl.
elongata, Bl.
megaptera, Bl.
Anenchelum Glarisianum, Bl.

The following are from the lithographic limestone of Solenhofen, Pappenheim, Manheim, and Eichstedt.

Clupra encrasicholoides, Germ.
dubia, Bl.
Knorrii, Bl.
Salmonea, Bl.
Davidei, Bl.
Pæcilea dubia, Bl. . . . . . . Anspach ?
Atherina Bavarica, Germ.
Esox avirostris, Germ.
acutirostris, Bl.
Stromateus hexagonus, Germ.
Ichthyolithus esociformis, Germ.
luciiformis, Germ.

And species supposed to belong to cyprinus ? perca ? squalus, zeus ? chætodon ? sparus.

General Summary.

Plants marine	4	These occur in the limestones.	
terrestrial cryptogamous	39	These are found in the sandstones and coal shales. The coal is principally composed of equiseta.	
gymnospermous	33		
monocotyledonous, &c.	4		
Polyparia fibrous	75	Conchifera brachiopoda	61
corticiferous and celluliferous	44	Mollusca gasteropoda	114
		cephalopoda	273
lamelliferous	59	Annulosa	55
Radiaria crinoidea	31	Crustacea	22
stellerida	7	Insects	
echinida	47	Fishes	40
Conchifera plagymyona	189	Reptiles	40
mesomyona	134	Mammalia	1

Total number of species 1272

It is impossible to close this extensive catalogue of the plants and animal remains of the oolitic period without acknowledging the great value of Mr. De la Beche's laborious investigations in this yet inexhausted field. In the German translation of his *Manual of Geology*, for which we are indebted to M. Von Dechen, are many important additions and improvements.

Cretaceous System.

Mineral character.

That a peculiar type, of mineralogical character, belongs to each system of formations, must have been sufficiently evident through the whole course of our investigation. The gneiss and mica slate system, the clay slate system, the limestones of the carboniferous system, the coloured marls and magnesian limestones of the saliferous system, the oolites, are all resting points for the mind, and amidst a multitude of shades and gradations, strongly impress upon us the distinctive features of the several periods of time at which these so different rocks were in a predominant degree produced.

Mineral characters alone, when rightly used, are in many instances sufficient to determine the Geological relations of even distant regions; and when conjoined with the evidence of organic remains, and controlled by careful survey of the strata above and below, they form a secure groundwork for topographical Geology.

The cretaceous system is equally definite as any of the others with respect to the distinctness of its prevailing mineral ingredients, and not less characteristically marked by peculiar marine exuviæ. Chalk and green sands are terms understood by all the Geologists of Northern Europe; and even on the Southern side of the Alps their representatives may be recognised.

Surface of country.

Through England, the ranges of chalk hills form a geographical feature even more important than that of the oolites; for though in general not so elevated, they are less interrupted and more extensive, more uniform in composition, and therefore more identical in aspect. The chalk hills form the first great ridge which is to be crossed from the Eastern side of the Island, and nothing can be more remarkable or instructive than such a journey. On approaching these broad hills from the level or gently undulated plains of the Eastern Counties, or the clay vales of the oolite system, the country changes entirely. The streams run in smoothly sloping valleys, the hills rise with beautiful swells into a long waving outline, seldom broken by a tree, but often capped by an ancient tumulus. Arrived on *the summit*, we behold a mighty extent of broadly undulated land with abundance of depasturing cattle, but few habitations of men. A variety of plants, eminently characteristic of calcareous soil, force themselves on the attention; flints abound in the fields, chalk is cut through in the roads, the soil is thin, the herbage short, the surface dry, and we feel ourselves in a new physical region.

This impression is confirmed when we observe more carefully the numerous undulations upon the surface of the "wolds;" for all these may be traced into connection as so many ramifications of greater valleys, which themselves often unite, and pursue a considerable course without enclosing even the smallest rill, or showing even the mark of a watercourse. These *dry valleys* descend from their origin in regular slopes, and are clearly the work of water, operating with great force, and for some time, but in the present system of Nature the watery agent has wholly disappeared.

The rains are absorbed as fast as they fall upon this dry surface, and sink to considerable depths in the rock, where they are treasured up in reservoirs to supply the deep wells and the constant springs which issue at lower levels.

In a word, broad, swelling hills, smooth, winding, often dry valleys, and a bare dry, grassy, surface, are the general features of the chalky districts.

This character of surface belongs, as Dr. Lister remarked long ago, to the chalk wolds of Yorkshire, Lincolnshire, Norfolk, Suffolk, Berks, Wilts. Dorset, Hampshire, Surrey, Kent, and Sussex.

Groups of the system.

The cretaceous system forms properly but one formation. Supposing the whole to be present in a single section, we should have the following general series.

Chalk group.	*f.* Upper chalk, with abundance of flints in layers and nodules.
	e. Lower chalk, with fewer flints.
	d. Chalk marl, or malm.
Green sand group.	*c.* Upper green sand, malm rock, or firestone.
	b. Gault clay.
	a. Lower green sand or iron sand.

d and *c* are sometimes *undistinguishable*. The lower green sand generally forms a distinct ridge, which may even exceed the chalk in height.

The complete system here presented occurs in many parts of Kent, Sussex, and Hampshire, but generally in other parts of England the sections are modified, so as to present only partial assemblages of the beds, sometimes one, sometimes another being deficient; and with respect to the malm rock, great differences being observable. Thus, in Wiltshire, where Mr. Smith took the type of this formation, we have the upper green sand remarkably developed; the lower one and the gault are contracted.

Chalk upper lower	500 feet.
Chalk marl	100
c. Green, grey, and yellow sand	120
Gault	50
Lower green sand	30

Along the line of chalk hills from the valley of the Thames to Lynn, the upper green sand is almost lost in the chalk marl and gault; green grains being mixed with the former, and still more in the upper layers of the latter. In Bedfordshire, the chalk marl produces a bed of silicious, chalky stone, which may probably be analogous to the firestone of Mesterham in Surrey, which is determined to belong to the upper green sand series. Indeed, the sections along this part of the chalk range are very similar to those of Sussex and Kent.

In Lincolnshire we meet with a new feature, a band of red chalk; at the base of that, thick rock; under this no upper green sand, and generally no gault, but the chalk rests upon a thick series of greenish and ferruginous sands, with included beds of sandy limestone, full of fossils resembling those of the lower green sand of Kent. This country has been very badly represented in all our maps.

In Yorkshire, the cretaceous system consists of

Upper chalk.

Lower chalk and traces of chalk marl.

Red band of chalk.

Gault with green grains passing downwards into Kimmeridge clay, without the intervention of the lower green sand.

From several recent researches abroad it has been thought that the chalk group of England and France is imperfect in the upper terms, and that the well-known Maestricht beds, and the recently investigated Gosau beds, appear to soften the transition from the chalk to the true tertiary strata. If Mr. Webster's observation of a supercretaceous marl in the Isle of Wight belong to this era, analogous deposits are not *absolutely* wanting in England. We shall now trace the history of these several members of the green sand and chalk groups, beginning as usual with the lowest.

The lower green sand. (Syn. Iron sand. Shanklin sands, &c.)

In Lincolnshire, the lower green sand is a considerable mass of yellow, often very irony sand, forming, toward the West, poor heaths upon the Kimmeridge clay, exactly like those about Lynn, Ampthill, and Godstone. It contains a good deal of bad ochre, very similar to that of Shotover Hill, and lines of oxyde of iron like that of Ryegate. Beds of grey stone, blue within, flat-bedded, sandy, and full of fossils, lie in it, and afford excellent road materials. These are dug at Tealby, Market Stainton, Ludford, Cawkwell, Blustone Heath, Stainton in the Hole, &c. It has considerable resemblance to the Kentish rag, and contains exogyra sinuosa, pecten cinctus, plagiostomata, serpulæ, ammonites, alcyoniform bodies, small corals, and many other fossils; but echini and belemnites appear unknown in it. From these details it is evident that the stratum has all the most decided characters of lower green sand. It is exposed by denudations in the chalk, and also ranges on the West of the wolds for a great length by Rasen, Lessington, Linwood, &c. to Louth. The whole thickness is probably 100 feet. These notices are partly derived from personal observation in 1821, but principally from a special visit to the district in 1833 with two friends, Messrs. Dikes and Lee of Hull, who have fully explored it.

As usual in coloured sands, this stratum often contains veins of perfectly white sand. At Lynn this has been found of value for the glass-houses. In Cambridgeshire and through Huntingdonshire, the iron sand forms a narrow course of low hills, but through Bedfordshire and Buckinghamshire it takes a commanding station, forming heathy ridges from Potton to Woburn, and through Buckinghamshire and Oxfordshire, capping Brickhill and Brill Hills, Shotover Hill, Cumnor Hurst, and Faringdon Clump. In Wiltshire, Spy Park, Bowood, Seend Hill, are capped by these beds, but they are supposed to thin out to the South, and to be lost, until in Blackdown they are probably associated with the upper green sand. In the Isle of Purbeck and the Isle of Wight it is an important rock, and, as observed before, encircles the whole of the Wealden formation of Kent and Sussex.

Through the whole of its range from Cambridgeshire into Wiltshire it is a highly ferruginous sand, with spheroidal or merely irregular concretions of oxyde of iron, frequently enclosing a coarse brown ochre. At Shotover, the fine yellow ochre forms two irregular beds, separated by a thin parting of clay. Fuller's earth also occurs in it in layers in Bedfordshire, especially at Woburn. Grains of green sand abound in some layers of these beds in Bedfordshire and Buckinghamshire, and constitute it a real green sand. Chert layers also are formed in it, and many of the beds assume the aspect of coarse conglomerate, used by the ancient Britons for the making of quern stones or carstones, whence Mr. Smith gave this name as a synonyme of the iron sand. Fossil wood is frequent in these beds. In Bedfordshire its thickness may be stated at 100 feet; in Wiltshire Mr. Lonsdale finds it 30.

In the Isle of Purbeck, the iron sand consists of many beds of quartzose conglomerate, and of coarse and fine grained sandstones, containing beds of wood coal. In the Isle of Wight, dark red ferruginous sandstones in the upper part, and alternations of red and yellow ferruginous sands and clays in the lower part, form the substance of all the Southern half of the Island, and contribute much to the beauty of the scenery of the Undercliff.

In its long course around the Wealds of Kent and Sussex, the lower green sand presents, with the general characters noticed above, some local peculiarities of interest. In Leith Hill, its extended plateau makes a commanding feature, and shows a great thickness of brown sands, with abundance of chert, with confluent grains passing into chalcedony, and some alcyonites like those of the Isle of Wight.

The importance of the lower green sand as a geographical feature diminishes as it proceeds round the South side of the Weald, but the Northern range is generally elevated and remarkably continuous by Ryegate, Nutfield, and Maidstone to Hythe and Folkstone. At Ryegate it is almost exactly like the ferruginous rock of Woburn; at Nutfield it produces beds of fuller's earth; from Maidstone to Hythe and Folkstone the sands are in general remarkably, and even excessively, rich in green grains and nodules, and contain beds of whitish limestone, sometimes chalky and often cherty, with green grains, considerably rich in ammonites, trochi, cardia, pectens, lutrariæ, exogyræ, echinites, and other fossils. These beds may be generally called Kentish rag. Some of them are of a dark grey colour, very hard, full of green grains, and rich in many fossils, some of which are usually found in the upper green sand. The cherty beds of Leith Hill and Haslemere are probably the representatives of these calcareo-silicious layers.

Some of the beds of lower green sand about Folkstone are excessively coarse in the grain, and absolutely crammed with green grains and nodules. The large species of exogyra is very frequent, and appears characteristic. The blue marl or gault rests immediately on the sandy beds.

The gault or golt. (Syn. Blue Marl of Tetsworth and Folkstone, Micaceous Brick-earth, Smith.)

The gault or golt is an argillaceous member of the green sand group, of great interest to the Conchologist, since in Kent, Surrey, Sussex, Wiltshire, Cambridgeshire, and Yorkshire, it yields a most rich supply of molluscous remains, many of them minute and of the greatest beauty. It accompanies the lower green sand around the whole district of the Weald, separates the upper and lower green sand in the Isles of Wight and Purbeck, and follows with the same relations the range of the green iron sand through Wilts and Berks, Buckinghamshire and Bedfordshire, and Cambridgeshire, and appears in Yorkshire without either upper or lower green sands immediately below the chalk. Its average thickness may be fairly estimated at 100 feet, and it universally forms a characteristic narrow valley under the chalk. No remarkable peculiarity of mineralogical aspect or chemical composition distinguishes the gault, except a general tendency to admit green grains into its more sandy portions. It produces a capital brick earth fit for white bricks, in the midland Counties. It is often of a very dark blue, but sometimes of a light grey colour. Near Folkstone it contains in the lower part a remarkable layer of small, irregular, ironstone nodules, every one of which is formed round an ammonite. A similar layer contains similar ammonites at Steppingley Park, Bedfordshire. At Specton in Yorkshire oval nodules of similar nature generally enclose small specimens of astacus. Small belemnites, hamites, ammonites, nuculæ, striated terebratulæ, serpulæ, &c. abound in the gault, and serve admirably to complete the catalogues of fossils of the cretaceous system.

The upper green sand

The upper green sand was first examined in Wiltshire, where it consists of green, grey, and irony sands, immediately subjacent to the chalk, and affording passages for the collected water of that thick deposit downward to the gault. The green grains there assumed to be characteristic of these strata are now known to occur in older sands, (in calcareous grit, for instance,) and in much more recent beds, (as above the chalk frequently,) yet still the greenness of the sands immediately below chalk is a curious general fact. They are, however, quite as often grey or even whitish, with a remarkable tendency in the grains to coalesce into meagre sandstone, sandy chert, and at length semitransparent and chalcedonic chert. These effects are particularly to be observed among specimens of the sponges, and so called alcyonia, which abound in the green sand group. It is easy to understand how so variable a mass of sands placed immediately below the chalk, and clearly in many places (as at Havre) graduating into that calcareous rock, should in several instances become so cretaceous as to be hardly distinguishable from the chalk itself. This happens in Bedfordshire, where the Tattenhoe stone appears to be the representative of the upper green sand, in Surrey at Merstham, in Dorsetshire at Beer. Round the Weald of Surrey and Sussex, the malm rock, which is certainly coeval with the Wiltshire green sand, (Murchison,) and also with the Merstham firestone, occasionally shows many green grains, and at Beechy Head (Mantell) changes to nearly the ordinary type of the green sand of Wiltshire. From these considerations we are fully justified in regarding the upper green sand as intimately connected with the lower commonly argillaceous part of the chalk, just as the calcareous grit is with the coralline oolite, and the calciferous sand with the inferior oolite. In particular places, mechanical causes gave a predominance to its sandy character, and in others the abundance of organic exuviæ impressed it with a particular zoological type. This mode of viewing it exactly accords with its general character through France, where it is associated with the lower argillaceous chalk under the title of *glauconie crayeuse*. According to this classification, the upper green sand or firestone beds form a nearly continuous base for the chalk from Lynn to Dorsetshire, and round the whole of the Weald of Kent and Sussex, yielding organic remains at intervals.

Chalk marl.

Chalk marl may be viewed as the next step in the gradation of changes by which we are conducted from the green sand system to the true cretaceous type. It is, in fact, an argillaceous chalk, holding variable quantities of clay and sand, superimposed upon the green sand or malm rock, and gradually changing upwards to the lower chalk. It is, perhaps, observable on the Western slopes of the Yorkshire wolds above the red chalk, but is distinctly traceable below nearly the whole range of the chalk hills from Lynn to Dorsetshire, and round the whole of the Weald, every where closely associated with, and indeed hardly separable from, the malm rock or firestone, and often enclosing, as near Woburn and Folkstone, green grains and fossils of the true upper green sand.

Were it not that all such classifications are arbitrary, and only locally exact or valuable, we might conveniently group together the upper green sand and chalk marl divisions, and thus rank together the greatest part of the lower fossiliferous beds of the chalk, which, occasionally argillaceous, stony, or sandy, appear very generally interposed between the true chalk and the continuous lower green sand.

Lower chalk.

In England, generally, the lower half of the thick mass of chalk is harder, more jointed, and less divided by layers of flint nodules than the upper part. It is often of a greyer colour, and, to a certain extent, distinguishable by a different suite of organic remains. In particular, it appears to contain very few of the stellerida, crinoidea, or echinida, not so many belemnites or terebratulæ, but, on the contrary, yields more ammonites, some hamites, trochites, and other fossils approaching to those of the green sand group below. But the mineralogical character of the lower part of the chalk is liable to great variations. In Yorkshire, three-fourths of the whole mass are hard, and the lower portions are as much traversed by layers of flint nodules, at pretty regular distances, as the upper parts. In the Dover cliffs, beds of soft cretaceous marl divide the chalk without flints into two portions, the upper one yellowish, hard, and containing numerous thin beds of organic remains, the lower one whiter, softer, often gritty at the top, enclosing masses of pyrites, but few organic remains. (W. Phillips, in *Geology of England and Wales.*)

The upper chalk is usually recognised in England by its whiteness, softness, numerous layers of flints at intervals of four to six feet, and abundance of zoophytic remains. Sponges of many kinds, small lamelliferous corals, millepores, crinoidea, stellerida, echinida of very remarkable form, large inocerami, belemnites, and abundance of terebratulæ are the most frequent of its numerous fossils. The layers of flint nodules are exceedingly interesting, and throw light upon the mode of formation of the chalk. They are always found in the planes of stratification, generally irregular in figure, black or grey within, with traces of spongiferous bodies, shells, echini, or other organic bodies. The external crust is usually white and silicious. The sponges also are often quite white and silicious, and lodged in a cavity, left by the decay of part of their substance. The crusts of echini are usually, even when enveloped in flint, converted to calcareous spar, and belemnites retain their original radiated structure. Occasionally, as at Sudbury, the flint occurs in thin layers parallel to the stratification.

It seems probable that in the formation of the chalk from the decomposition of the sea-water then holding lime and silica in solution, the carbonate of lime and silica fell to the bottom together, in quantities sufficient on each occasion to constitute a *bed* of chalk and flint, and that the latter substance was especially attracted by the organic remains then lying on or beneath the beds, so as to collect round the sponges, echini, &c., exactly as the oolitic matter has been collected round shells, the lias limestone round ammonites, the carbonate of iron round ferns, &c. Analogous cases occur in the spongiferous cherts of the Portland oolite and coralline oolite, and we might perhaps venture to extend the same mode of reasoning to the case of chert nodules in carboniferous limestone, for these often (not so generally as in the case of flint) contain organic remains.

Pyrites is generally plentiful in the upper chalk, variously crystallized, and is not unfrequently associated with silica in the sponges which lie in chalk. It is in these cases generally decomposed into brown oxide of iron.

Flints are very often split or cracked in their native repositories, as if by contraction of the mass, and this sometimes, but less frequently, happens, when organic remains of a solid kind are enclosed in them. The most remarkable cases of this nature are described by Mr. Webster, in the dislocated upper strata of chalk in the Isle of Wight. All the flints in the layers which alternate with chalk, are found broken in every direction into pieces of every size, which remain in their relative places enclosed within the cell of chalk, and showing no other signs of fracture than a fine line, as in shivered glass. On being removed from their place the flints fall into many pieces. This singular fact seems connected with the disturbances of the chalk, and may, perhaps, be due to the violence of the tremour then impressed upon the mass, a tremour which might shiver elastic flint, (especially if, like a Rupert's drop, its particles had been previously in a state of tension,) but leave the chalk unaffected.

Mr. Webster's account of a bed of argillaceous chalk or marl in the Isle of Wight, above the chalk with flints, seems to be the only indication of a transition or gradation of deposits between the chalk and the tertiary beds yet clearly observed in England. The marl dug on the Sussex Downs, as well as that in Hertfordshire and Norfolk, may, perhaps, be related to it.

Range of the Cretaceous System out of England.

The principal range of the cretaceous rocks is included within the general boundaries of the European basin, and it is probably not at all less extensive than the oolitic system, though by the diffusion of tertiary rocks above it, its course in large tracts of country is wholly subterranean.

Ireland.

The cretaceous system of Ireland is in a depression, on the Western side of what is usually understood by the basin of Europe. It consists of chalk 200 or 300 feet thick, harder than is common in England, but with a similar though less extensive suite of organic remains, and rests on green sand, there called *mulatto*, with the usual characters of that group in England. Lias is found beneath at the Giant's Causeway. In Scotland, only a very dubious indication of the cretaceous system is afforded by the flints which rest upon primary rocks near Peterhead.

Within the natural modern boundaries of the principal basin of European secondary strata, the primary rocks of Scotland, Cumberland, Wales, Cornwall, and Brittany, on the West; the Pyrenees, the Alps, and the Carpathians, on the South; Caucasus and Oural on the East; Finland and Scandinavia on the North; the cretaceous system, chalky, marly, or sandy, is very largely developed. The type of the formation may be taken in Southern England or Northern France indifferently. In the latter Country its extent on the surface is probably equal to the whole superficial area which it occupies elsewhere in Europe. It encircles with a broad belt the basin of Paris, and passes off on the North-Eastern side into Belgium, which whole Country it probably underlies, though the tertiary deposits conceal it, except along the sides of the Meuse. At Maestricht the upper beds of the cretaceous formation have, in many respects, mineralogical and organic, a remarkable analogy to the *calcaire grossier*, which is the lowest really marine tertiary rock in the vicinity. These beds, however, by their principal characters really belong to the cretaceous system, of which they may be considered the highest terms at present known. A little appearance of the chalk is observable North of the coal of Elberfeld, to which it is unconformed, as well as to that of Namur and Liege. The chalk system most probably underlies the whole region of Northern Germany, from the point last mentioned North of the oolite and lias of Westphalia. The green sand is remarkably well exhibited with characteristic fossils in the romantic tract of Saxony, North of the Erzgebirge, (there called *quadersandstein*,) as well as an upper calcareous portion supposed equivalent to the chalk and planerkalk. North of the Carpathians, both chalk and green sand occur in long ranges of hills, passing from Poland by Lemberg into Podolia and the South of Russia. It reaches the Dneister, and extends to the plains of Volhynia. It forms considerable eminences around Grodno in Lithuania. " Further South, in the plains of Moldavia, Podolia, and Bessarabia, it appears only in detached portions. Chalk is found on the Southern side of the granitic Steppe in the Crimea, and on the borders of the Sea of Azof, between the Berda and the Don. In the Country of the Don Cossacks, in the Governments of Woronack, Koursk, and Toula, it appears in hills and on the banks of rivers, and probably constitutes the base of that great and fertile plain." (Pusch, quoted by De la Beche, *Manual of Geology.*)

In Pomerania and Mecklenburg, and the Island of Rugen, cliffs of chalk occur with the usual fossils of England, and in Sweden it rests upon rocks of gneiss and greywacke, and only in one instance, at Limhamm in Scania, upon rocks of the oolitic era. In the North of Germany it appears at intervals, near Luneburg, and on the borders of the Harz mountains, (at Quedlinburg,) and there seems no reason to doubt that the whole vast plain of Northern Germany, from the Rhine to the Vistula, rests upon the cretaceous system. What remains of the Island of Heligoland consists of green sand.

The whole line of the Alps from the Salève to Vienna is bordered upon the Northern side by rocks of the cretaceous system, which are closely associated in character with both the oolites beneath, and with the tertiaries which lie above A similar observation applies to the South side of these mountains; chalky rocks range down the Apennines, and occur abundantly in the Maritime Alps, there, as well as about Geneva, intimately associated with the upper oolitic beds. Deposits of this era also lie in old valleys of the Jura mountains, which range in a North-Eastern and South-Western direction. The Pyrenees are bordered on both sides by green sand and sandy and calcareous beds, containing with many chalk fossils some of tertiary types.

Over this extensive area the mineralogical characters of the system are tolerably uniform, except in the vicinity of the Alps, where the violent disturbances to which that mountain range has been subjected appear to have entirely altered the aspect of these beds, so as to permit authors to speak of *black chalk*, which, however, is perhaps a portion of the green sand group. Over all the region already mentioned in France, in Belgium, at all the points in Northern Germany, in Poland, in Russia, Pomerania, Denmark, and Sweden, the chalk has its usual characters and appearance, and contains ananchytes and spatangi, belemnites, terebratulæ, inocerami, &c. The green sand in France, near Aix la Chapelle, along the Erzgebirge, in Poland, along the Carpathians, in Heligoland, has its usual characters. Indeed, even along the Eastern Alps, but especially in the Swiss and Savoy Alps, and the Jura, the green sands' group retains nearly its usual aspect, and exhibits its usual fossils; and an English Geologist placed at the Perte du Rhône, or amidst the relics of the Montagne de Fiz, is at once introduced to the Geology of the vicinity. Green sand layers alternate with the upper part of the Jura oolites in the Salève, and the same phenomenon appears to happen along the Eastern Alps, (Murchison's and Sedgwick's Memoirs, *Geological Transactions,*) where some parts of this group contain fuci so as to be characterised thereby. Nummulites are associated with the green sand in the Swiss Alps, and also in the Maritime Alps, where the lower beds of the cretaceous formation consist of light-coloured limestone charged with green grains, and full of belemnites, ammonites, nautili, and pectines, and appear intimately connected with the top of the Jura limestone deposit. (De la Beche, *Manual*, 259.) Nummulitic rocks, calcareous and arenaceous, exist in Dalmatia, and form high mountains in Croatia.

On the Southern side of the Alps, the beds of the cretaceous era, which descend to the plains of Lombardy, are principally composed of white, greenish, and reddish beds, and it appears that a gradation of character may be traced through the oolitic, cretaceous, and tertiary strata here uplifted. (Murchison.) Some of the light-coloured limestones referred to the chalk are called scaglia, and the mountain of the Voirons near Geneva, yields a rock of similar nature.

Dislocations of the Cretaceous System.

Like the oolitic era, the cretaceous period appears to have been one of regular action, perhaps still more uniform than that, but not of so long duration. For we do not find its deposits to contain so many distinct suites of organic remains, nor so many remarkable *repetitions* of analogous rocks as occur in the oolitic system. The lower sandy beds of the system, indeed, may be thought to have been influenced by the convulsions which upheaved the oolites, but we cannot assent to the notion of Elie de Beaumont, that the whole cretaceous system is derived from the mechanical movements thus impressed upon the waters. The organic remains of the system sufficiently disprove this, and the great extent and uniformity of the deposit of chalk is no otherwise to be explained, than by general laws applicable to all the older and more recent calcareous strata.

That disturbances of great extent happened *somewhere* after the deposit of the chalk in England, is evident from the extraordinary abundance of sandy and gravelly accumulations, sometimes resting in hollows of the chalk, which immediately cover that stratum. A great part of the plastic clay group is of this fragmentary and tumultuary origin, and its black flint pebbles are only water-worn chalk flints. But England does not appear to have been the centre of these convulsions, nor to have been much moved by them unless bodily, and without local and violent fracture of strata. It is, indeed, very *probable*, that parts of the chalk formation, originally deposited in deeper seas, were at this time brought up and made to constitute a shore and to be liable to all the waste of the waves. And some portions might be, and probably were, raised to dry land, and exposed to the weather and the wearing of streams. But we cannot at present undertake to say where such a shore occurred, nor in what part exactly the chalk was raised into hills.

In Ireland, at this period, great eruptions of basalt happened, and broad lakes of lava covered the chalk of that Country.

In France the chalk was wasted as in England, and its flints rolled to pebbles, to constitute the pebbly beds of the plastic clay group; and this seems to have been chiefly effected by fresh-water streams, for we find in the plastic clay of France few organic remains besides terrestrial and fresh-water productions. Yet here, we believe, it is equally difficult to say what *portions* of the chalk were thus raised and exposed. The surface of the chalk in France appears to have been more wasted and furrowed than in England.

To this period, Elie de Beaumont ascribes the dislocations which in the French Alps and the South-Western extremity of the Jura, from the environs of Antibes to those of Pont d'Ain and Lons le Saulnier, present a series of dislocations in a direction North North-West. The primary mass of Mont Viso is traversed by this system of faults. The Eastern crests of the Devolny on the North of Gap, are formed of the oldest beds of the green sand and chalk, thrown up in the direction

North North-West, and raised more than 4700 English feet above the sea, while at their feet, and 2000 feet lower, the nummulitic or upper portion of the cretaceous system remains horizontal and entirely undisturbed.

Every thing belonging to this particular epoch, that is calculated to throw light on the changes then operated on the external features of the Globe, is of the highest curiosity and importance, since the probability is great that very violent and extensive convulsions, producing most remarkable alterations in Physical Geography and in other conditions of organic life, must have happened to occasion so entire and sudden a change of plants, shells, and vertebrated animals, as, notwithstanding recent discoveries of supposed intermediate strata, is admitted to have taken place after the deposition of the cretaceous system.

Some time after the above remarks were written, the third volume of Mr. Lyell's *Principles of Geology* appeared, in which that able Geologist has ventured to do what we thought too difficult to attempt, and defines in one instance what part of the ancient bed of the sea was raised at the commencement and during the continuance of the tertiary period. Combining his own observations on tertiary strata with Mr. Mantell's discoveries, he proposes the theory that the elevation of the Wealden district of Sussex and Kent was contemporaneous with, or only immediately antecedent to, the deposition of the tertiaries in those parts of the sea which are now become the basins of London and Hampshire; that the elevation of the secondary, as well as the deposition of the tertiary rocks, was produced by long continued operations of the same kind, and that as different strata were raised in the Weald, to be wasted away by the sea and atmospheric action, the tertiary deposits, thence carried to the depths of the sea, were proportionately varied. We cannot now discuss this ingenious theory, because it is connected with a very extensive argument, involving many of the fundamental views of this author, Elie de Beaumont, and Von Buch, but it will be examined in its proper place.

Table of the Organic Remains of the Cretaceous System.

PLANTS, (from M. Adolphe Brongniart.)

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Confervæ.	Confervites fasciculata		Sussex	chalk	Arnager in Bornholm.
	ægogropiloides			ditto	Ditto.
Algæ	Fucoides Brardi				Pialpenson. (Dordogne.)
	Orbignianus				Isle d'Aix, near La Rochelle.
	strictus				Isle d'Aix.
	tuberculosus				Ditto.
	Targionii	chalk	Bognor, Sussex		Les Voirons, near Florence.
	æqualis				Vernasque in the Plaisantin.
	difformis				Bidache, near Bayonne.
	intricatus				Oneille, Genoa, Florence, Vienna, Bidache.
	furcatus				Vernasque, Gênes, Florence.
	recurvus				Vernasque.
	Lyngbianus				Arnager.
	Brongniarti, Mant.	ditto	Sussex.		
Naiades	Zosterites caulinæfolia				Isle d'Aix.
	lineata				Ditto.
	Bellovisiana				Ditto.
	elongata				Ditto.
Cycadeæ	Cycadites Nilsonii			chalk	Scania.
	Thuytes aliena, Sternb.			planerkalk	Schmetschna.
	Wood, dicotyledonous	ditto	ditto.		
Leaves resembling platanus and liriodendron, Sternb.					Blankenburg, Wernigerode.

It does not appear that any of the plants of this epoch were in existence before or since.

POLYPARIA.

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Fibrosæ	Spongia plana, Phil.	chalk	Bridlington.		
	capitata, Phil.		Ditto.		
	osculifera, Phil.		Ditto.		
	convoluta, Phil.		Ditto.		
	lobata, Flem.		Lewes, Norwich.		
	marginata, Phil.		Bridlington.		
	radiciformis, Phil.		Ditto.		
	terebrata, Phil.		Ditto.		
	porosa, Phil.		Ditto, Dover.		
	lævis, Phil.		Bridlington.		
	cribrosa, Phil.		Ditto.		
	ramosa, Mant.		Ditto, Sussex		Noirmoutier.
	paradoxica		Hunstanton, Southbourn.		
	(Spongus) labyrinthicus, Mant.		Heytesbury, Lewes.		
	Townsendi, Mant.		Ditto, ditto.		
	(Siphonia) Websteri	green sand.	Isle of Wight, Southbourn.		
	curvicornis, Goldf.			marl	Westphalia.
	incrassata, Goldf.			chalk	Ditto.
	(Ventriculites) Benettiæ, Mant	chalk	Lewes, Wilts, Bridlington.		
	radiatus, Mant.	ditto	Lewes.		
	alcyonoides, Mant.	ditto	Ditto, Warminster.		
	quadrangularis, Mant.	ditto	Offham, Sussex.		

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Fibrosæ	(Choanites) subrotundus, Mant.	chalk	Lewes.		
	flexuosus, Mant.	ditto	Ditto.		
	Kœnigi, Mant.	ditto	Warminster, Lewes.		
	Halirrhoa costata, Lam.	green sand	Warminster		Normandy.
	Paramoudra	chalk	Belfast, Norfolk.		
	Alcyonium globulosum, Defr.	ditto	Sussex		Beauvais, Meudon, &c.
	pyriforme, Mant.	ditto	Ditto.		
	Serea pyriformis, Lam.	green sand	Warminster.		

Of the following fibrous polyparia described by Goldfuss from Maestricht and Westphalia, it is very probable that when better known, several will be found identical with the spongiæ and alcyoniæ of English authors. It is to be regretted that the labours of Naturalists in this difficult branch of fossil Zoology have been almost fruitless for want of cooperation. The abundance of spongoid fossils is a very remarkable character of the English and Westphalian chalk.

Achilleum glomeratum	Maestricht.
fungiforme	Ditto.
morchella	Essen.
Manon capitatum	Maestricht.
tubuliferum	Ditto.
pulvinarium	Ditto, Essen.
peziza	Ditto, ditto.
stellatum	Essen.
pyriforme	Coesfeld
Scyphia fungiformis	Ditto.
Mantellii	Ditto.
Dechenii	Ditto.
Oeynhausii	Darup.
Scyphia Murchisonii	Darup.
verticillata	Maestricht, Nehou.
mammillaris	Essen.
tetragona	Ditto.
furcata	Ditto.
foraminosa	Ditto.
infundibuliformis	Ditto.
Sackii	Ditto.
Tragos deforme	Ditto.
rugosum	Ditto.
pyriforme	Ditto.
stellatum	Ditto.
hippocastanum	Ditto.

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Carnosa.	Chenendopora fungiformis, Lam.	green sand.	Warminster.		
	Hippalimus fungoides, Lam.		Ditto.		
Corticifera	Gorgonia bacillaris, G.			chalk	Maestricht.
	—— Phil.	chalk	Bishop's Wilton, Hants.		
Cellulifera	Millepora Fittoni, Mant.	ditto	Sussex.		
	Gilberti, Mant.		Ditto.		
	antiqua? Defr.				Normandy.
	—— Bl.				Meudon.
	compressa				Maestricht.
	madreporacea				Ditto.
	Nullipora racemosa				Ditto.
	Eschara cyclostoma				Ditto.
	pyriformis.				Ditto.
	stigmatophora				Ditto.
	sexangularis				Ditto.
	cancellata				Ditto.
	arachnoidea				Ditto.
	dichotoma				Ditto.
	striata				Ditto.
	filograna				Ditto.
	disticha				Meudon.
	Cellepora ornata				Maestricht.
	hippocrepis				Ditto.
	velamen				Ditto.
	dentata				Ditto.
	crustulenta				Ditto.
	bipunctata.				Ditto.
	escharoides				Essen.
	—— Phil.	ditto	Knapton, Yorkshire.		
	Retepora clathrata				Maestricht.
	lichenoides				Ditto.
	truncata				Ditto.
	disticha				Ditto.
	fenestrata				Nants.
	cancellata				Maestricht.
	Coscinopora infundibuliformis.			marls.	Coesfeld.
	macropora			ditto	Münster.
	Coeloptychium agaricoides			ditto	Coesfeld.
	Flustra reticularis, Lam.	ditto	Sussex, Norwich.		
	reticulata, Desm				Normandy.
	flabelliformis, Lam.				Ditto.
	tessellata, Woodw.	ditto	Norwich.		
	Ceriopora cryptopora			chalk	Maestricht.
	micropora.				Ditto, Essen, Nantu.
	anomalopora				Maestricht.
	polymorpha			marl	Essen.
	*dichotoma				Maestricht.
	milleporacea				Ditto.

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Cellulifera	Ceriopora gracilis				Essen.
	madreporacea			chalk.	Maestricht.
	tubiporacea			ditto	Ditto.
	spongites			marl	Essen.
	*clavata				Ditto.
	cribrosa				Ditto.
	verticillata			chalk.	Maestricht.
	spiralis				Ditto.
	pustulosa				Ditto.
	compressa				Ditto.
	trigona			marl	Essen.
	stellata			chalk	Maestricht, Essen.
	*diadema				Ditto.
	mitra			marl	Essen.
	venosa				Ditto.
	Lunulites cretacea, Defr.				Maestricht, Tours, Normandy.
	Orbitolites lenticulata	chalk	Sussex.	green sand.	Perte du Rhone.

Celluliferous polyparia appear at present scarce in the English chalk and green sand, yet probably, on further research, the contrast which in this respect subsists between our series and that of Maestricht and Westphalia may be diminished.

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Lamellifera	Lithodendron gracile			green sand.	Quedlinburg.
	(Caryophyllia) gibbosum				Near Bochum, Westphalia.
	Caryophyllia centralis, Mant.	chalk	Sussex, Yorkshire, Normandy.		
	conulus, Phil.	gault	Yorkshire, Cambridgeshire.		
	Fungia radiata			chalk	Aix la Chapelle.
	cancellata				Maestricht.
	coronula			marl	Essen.
	(Turbinolia) Kœnigi	chalk	Sussex.		
		green sand	Wilts.		
		gault	Cambridge, Yorkshire.		
	Diploctenium cordatum			chalk	Maestricht.
	pluma				Ditto.
	Meandrina reticulata			ditto	Maestricht.
	Astræa flexuosa				Ditto.
	geometrica				Ditto.
	clathrata				Ditto.
	escharoides				Ditto.
	textilis				Ditto.
	velamentosa				Ditto.
	gyrosa				Ditto.
	elegans				Ditto.
	angulosa				Ditto.
	geminata				Ditto.
	arachnoides		?		Ditto.
	rotula				Ditto.
	macrophthalma				Ditto.
	muricata				Meudon.
	stylophora				Ditto.
	Pagrus Proteus, Defr.				Ditto, Tours, Normandy.

It is probable that the whole suite of polyparia of the cretaceous system is peculiar to it. This remark is meant to apply to the Maestricht fossils as well as to the more generally recognised types of chalk and green sand.

RADIARIA.

Family.	Name.	Rock.	Foreign Localities.	Rock.	British Localities.
Crinoidea	Apiocrinus ellipticus	chalk	Sussex, Wiltshire, Yorkshire	chalk	Touraine, Normandy.
	Pentacrinus caput Medusæ	gault	Yorkshire	ditto	Maestricht.
	Marsupites Milleri, Mant.	chalk	Ditto, Wiltshire, Sussex.		
	Glenotremites paradoxus, G.			marl	Speldorf, near Mulhausen.
Stellerida	Asterias quinqueloba			chalk	Maestricht, near Munster.
	———	ditto	Norwich, Wiltshire		Paris, Rouen, &c.
	regularis, Wood.		Swaffham, Lewes.		
	semilunatus	ditto	Norfolk, Wiltshire, Yorkshire.		
	lentiginosus, Wood.		Dover.		
Echinida	Cidaris regalis			ditto	Maestricht.
	scutigera				Kehlheim, Bavaria.
	crenularis				France.
	granulosa				Aix, Maestricht, Essen.
	variolaris			marl	Essen, Coesfeld.
	ornata				Essen.
	papillata, Park	ditto	Wiltshire, Sussex, Yorkshire.		
	mammillata, Park		Wiltshire.		
	cretosa, Mant		Lewes, Northfleet.		

Family.	Name.	Rock.	British Localities.	Rock.	gn Localities.
Echinida...	Cidaris variolaris (*G. Trans.*)		Lewes, Lyme	chalk	Havre.
	vulgaris, Lam.				Poland.
	asterizans	green sand.	Warminster.		
	corollaris, Mant.	chalk	Sussex, Wiltshire, &c.		
	clavigera, Kœnigi		Sussex.		
	vesiculosa			marl	Essen.
	Echinus saxatilis, Park	ditto	Sussex, Norwich.		
	Kœnigi, Mant.		Sussex, Yorkshire		Moen.
	Benettiæ, Kœnigi	green sand.	Wiltshire.		
	areolatus, Wahl.		Ditto, Lyme Regis	chalk	Bodsberg in Scania.
	alutaceus			marl.	Essen.
	granulosus			sandstone	Kuhlheim.
	radiatus			marl	Essen.
	Clypeus, small species	ditto	Warminster.		
	Clypeaster Leskii			chalk	Maestricht.
	fornicatus				Munster.
	Galerites albogalerus, Leske	chalk	Lewes, Wiltshire, Yorkshire	ditto	Aix, Poland, Dieppe, &c.
	subrotundus, Leske		Lewes, Norwich, Yorkshire.		
	vulgaris, Lam		Lewes, Lyme		Aix, Dreux.
	conoideus			ditto	Perigord.
	subuculus, Lam		Wiltshire	green sand and marl	Havre, Coesfeld, and Essen.
	depressus, Lam				Fiz, Swisserland, Bavaria.
	canaliculatus				Buren and Brunken, Paderborn.
	sulcato radiatus			chalk	Maestricht
	Hawkinsii, Mant	ditto	Sussex.		
	abbreviatus				Aix la Chapelle, Quedlinburg.
	Echinoneus subglobosus			ditto	Maestricht.
	placenta				Ditto.
	lampas, De la Beche	green sand.	Lyme Regis.		
	peltiformis, Wahl				Scania.
	Nucleolites depressus			ditto	Aix la Chapelle ?
	ovatus, Lam				Maestricht.
	scrobiculatus, Lam.				Ditto.
	pyriformis				Ditto.
	lacunosus			marl	Essen.
	cordatus				Ditto.
	carinatus			chalk	Aix, Hildesheim, Essen.
	lapis cancri				Aix, Maestricht.
	*testudinarius				Ratisbon.
	rotula, Bt.				Rouen, green sand, Mtn. de Fiz.
	castanea, Bt.			green sand	Mtn. de Fiz.
	patellaris			chalk	Maestricht.
	Ananchytes ovatus, Lam.	chalk	Sussex, Wiltshire, Norwich, Yorkshire, &c.	ditto	Meudon, Sweden, Lublin chalk, marl, Essen.
	hemisphæricus, Mant		Sussex, Yorkshire.		
	intumescens, Phil		Yorkshire.		
	pustulosus, Lam.		Norfolk	ditto	Paris, Rouen, Moen.
	conoideus				Aubel in Limburg.
	striatus				Aix, Maestricht.
	corculum			marl	Coesfeld.
	other species, Smith	ditto	England.		
	Spatangus ornatus, Cuv.	green sand.	Lyme		Aix, Biaritz, near Bayonne.
	suborbicularis, Defr.		Ditto		Maestricht, Dives.
	argillaceus, Phil.	gault	Wiltshire, Yorkshire.		
	Murchisonianus, Mant	green sand.	Nursted, Southbourn.		
	cordiformis, Mant.	chalk	Middleham, Norwich.		
	rostratus		Brighton, Norfolk		Joigny.
	prunella, Lam.		Brighton		Maestricht.
	cor anguinum, Lam.		Norwich, Lewes, Lyme, &c.		Paris, Normandy, Burgundy, Fiz, Coesfeld, Saxony, Bohemia.
	planus, Mant.		Yorkshire, Sussex		Scania, Poland.
	hemisphæricus, Phil.		Yorkshire.		
	lævis, Defr	ditto	Lyme	green sand	Perte du Rhone.
	bufo, Bt.			chalk	Paris, Normandy, Maestricht.
	——, Phil.	green sand.	Chute Farm, Wiltshire.		
	granulosus			ditto	Maestricht.
	subglobosus, Leske				Quedlinburg, Büren.
	nodulosus				Essen.
	radiatus, Lam.				Maestricht.
	bicordatus				Mecklenburg.
	truncatus				Maestricht.
	Bucklandi			marl	Essen.
	arcuarius, Lam. a recent species			chalk	Maestricht.
	amygdala, Lin.				Ditto.
	gibbus, Lam.				Paderborn.
	cor testudinarium				Maestricht, Quedlinburg, Coesfeld.
	bucardium				Aix.
	lacunosus, Lin.				Aix, Quedlinburg.
	retusus, Park.	ditto	Wilts.		
	punctatus, Park		Ditto.		

The distinctness of the form and characters of the incrusted radiaria, permits in general a satisfactory decision concerning their specific identification. On this account, no less than from the general diffusion of these fossils, the echinida, stellerida, and crinoidea ought to afford the most certain evidence concerning the laws of geographical distribution of animals during the cretaceous epoch. It cannot escape notice that a great number of species of echinida belong to extinct genera. It is remarkable that the genus spatangus, of which one or two species occur in oolite and several exist in the present seas, seems to have arrived at its maximum of abundance in the cretaceous epoch; and that the extinct genus, ananchytes, which is especially abundant and widely diffused in chalk, has not been found in the subjacent oolites, nor in the true tertiaries above the Maestricht beds. It is possible that amongst the echinida a very few species are identical with some found in the oolitic strata, (as galerites depressus, cidaris variolaris, &c.) but in general the species appear to be decidedly peculiar.

Conchifera.

Family.	Name.	Rock.	British Localities.	Rock.	Foreign Localities.
Plagymyona	Fistulana pyriformis, Mant.	gault.	Willingdon, Sussex.		
	personata, Mant.	chalk	Sussex.

Of 100 conchifera belonging to the chalk system, 32 are plagymyonous, 10 mesomyonous, 5 imperfectly known are classed as rudista, and 23 brachiopodous. They are mostly unknown in the strata above or below. The great predominance of mesomyonous bivalves is a feature common to this and the oolitic system. It must be remarked, however, that it is particularly difficult to settle accurately the number of species of the genera ostrea, exogyra, and inoceramus.

	Lamberti ?			chalk	Maestricht. (Hæn.)

The numerical predominance of the holostomatous gasteropoda over those which have a notched or canaliferous mouth, is rather less conspicuous in the chalk than in the oolitic rocks; but yet it forms a remarkable contrast with the enumeration of species in the tertiary deposits. Probably all the species are peculiar.

	———			green sand.	Alps of Savoy, Dauphiné, and Provence, Maritime Alps; chalk, Wimbohla, Saxony, Pyrenees.

The cephalopoda of the cretaceous system are mostly peculiar to it; and not only minutely, but very obviously, and often generically characteristic of it. Hamites, baculites, scaphites, turrilites, the dentated ammonites of Von Buch, are exclusively confined to the gault, green sands, and chalk. It is very remarkable how nearly the whole series of ancient cephalopoda ends with the chalk, and without being represented, except in a very small degree, by new forms of the same class, seems to yield place to a vast augmentation of the number of the gasteropodous mollusca, which through all the tertiary system maintain that numerical predominance over the conchifera which is observed in the actual system of Nature. The names in the preceding lists are chiefly taken from Sowerby's *Mineral Conchology*.

ANNULOSA.

Name.	Rock.	In British Localities.

fluctuata	ditto	Norwich.
macropus	ditto	Norfolk.
spirulæa	ditto	Norwich.
granulata	ditto	Ditto.
plana, Woodw.	ditto	Ditto.

The difficulty of determining species in these variable shells is such, as to throw great doubt over these determinations, made for the most part from single specimens. Objections of the same kind strike us on examining the twenty-one species of annulosa figured by Goldfuss from the cretaceous strata of Westphalia and Maestricht. The following list contains their names and localities.

Name.	Rock.	In Foreign Localities.

GENERAL SUMMARY.

Plants	22	species, chiefly marine.
Polyparia	142	52 fibrosa and carnosa, corticifera, 2. 61 cellulifera. 27 lamellifera.
Radiaria	95	
Conchifera	311	99 plagymyona. 123 mesomyona. 17 rudista. 72 brachiopoda.
Mollusca	206	73 gasteropoda. 133 cephalopoda.
Cirripeda	2	
Annulosa	37	
Crustacea	13	
Fishes	7	
Reptiles	8	
	843	species, almost exclusively marine.

Tertiary System.

We have now arrived at the last system of strata deposited in the sea and in lakes; before, as is usually stated, the present races of land animals and plants were called into existence. It is usually stated to be limited as to time between the era of the chalk and the beginning of the modern zoological period; but this definition is something arbitrary in application. As we have seen, on previous occasions, the several systems of strata, however distinct in the great mass, gradually soften into each other at the lines of junction, and sometimes exchange beds, so as to form the whole into a natural and connected series, so it may be with the present set of deposits in relation to the chalk. In England, indeed, as already remarked, this kind of *transition* from the chalk to the tertiaries, is nowhere distinct, nor are we entitled to say decidedly that at any point on the Continent of Europe it is well ascertained.

The blending, however, of tertiary and cretaceous rocks would, if established at many points, occasion no peculiar difficulty in their arrangement, nor alter one just inference drawn from previous observations. It is to be expected from every thing that is known of similar cases, that the great and abrupt change between the chalk and tertiaries in England and in France will be in some other Countries divided into easier gradations, and thus the maxim *natura non facit saltus*, will be found to prevail in this case as in all others.

A greater difficulty however occurs when we attempt to mark the ***modern limit*** of the tertiary system of strata, arising out of several circumstances important in their history, which scarcely required notice amongst the older deposits.

The ancient systems of strata were almost entirely marine; but

1. The tertiary system includes not only marine, but lacustrine deposits, which sometimes alternate with the marine strata, sometimes appear unconnected with them, and in several instances were evidently altogether independent of them and of each other, being formed separately upon the elevated lands under the influence of the ordinary processes of drainage. Now as similar causes have been in operation long since the tertiary era, and are in operation at present, it is often for this reason very difficult to say what is really the Geological antiquity of a lacustrine deposit, whether it be of the present epoch, or belonging to the tertiary or some intermediate system.

2. Within the tertiary era a variety of land mammalia came into existence which are now extinct, and which it appears had become extinct before what is called the diluvial detritus was scattered, and the elephant and hyæna were destroyed in Northern climes. If instead of antediluvian we should say mastozootic, and instead of tertiary, palæotherian, the generally received inference on this subject is, that the two periods are clearly and distinctly defined. Most of the observations support this view; but in a few cases palæotherian and mastozootic remains occur together, and are supposed to prove that the changes from the earlier to the latter system of organic nature were, like all the preceding, gradually accomplished; that before the palæotheria had become extinct, the ox, mastodon, and rhinoceros had begun to exist.

3. But allowing, for the present, that the palæotherian and mastozootic remains are of different ages, and agreeing by these characters to separate the diluvial from the tertiary deposits; how are we to apply this distinction drawn from the quadrupedal tenants of the land to the marine strata, in which their remains hardly ever occur? Or if, as in England we find quite easy, we should characterise the diluvial deposits by the mode of their occurrence over all the marine strata, what is to be done with strata like the Sicilian tertiaries, which have perhaps no contemporaneous analogue raised above the sea, and are supposed to show no trace of diluvial currents?

4. The tertiary class is often supposed to include only the deposits which happened before the present system of organic nature was established. But do Geologists really admit what these words imply? We who have used these terms, and have come to reflect on their meaning, answer certainly not, either in theory or in practice. For the *present system of organic nature* is most certainly recognised in nearly all the marine tertiary strata, if we trust to the evidence which in every other such case has been thought the best: *viz.* the marine shells. The shells of all the tertiary marine strata are proved by various degrees of evidence to belong to the present *system* of organic nature, for the genera are almost universally the same, though the numerical analogy of the species is very unequal in different deposits.

Neither is it true, that what are called lacustrine tertiaries can in all cases be pronounced to contain exuviæ of another system of organic nature; for if this could hardly be asserted of the basin of Paris, what is to be said of Aix and Œningen?

We come now to the terrestrial accumulation, that is to the diluvial and alluvial aggregates, containing bones of quadrupeds in characteristic abundance, and combining with these the notices of similar remains in lacustrine and marine deposits, the causes of past ambiguity, and the hope of future distinctness appear together. It can hardly be doubted that the land accumulations are capable of being classed by the reliquiæ of land animals which they contain; and this classification gives us the diluvial era, clearly separate both from the more recent and (if there be any remains of such) the more ancient alluvial periods. But this distinction of the races of land animals into periods, applies only to the land, and the extension of this classification to the productions of the sea can only cause utter confusion, and distrust of the inferences to which more legitimate processes would probably conduct us. In a less degree the same confusion will arise from applying this classification to fresh-water deposits, as the mixture of extinct quadrupeda and recent mollusca at Market Weighton in Yorkshire fully proves.

To be consistent, we must certainly allow that the races of land animals might be altogether changed without any corresponding change of lacustrine or marine shells, and we must limit our classifications to their just application. We must judge of the age and other characters of supracretaceous marine strata by comparison with what is known of the modern condition of the sea; the lacustrine deposits of the same era must be compared to the standard of the modern lakes; and the terrestrial accumulations will derive illustration from comparison with the modern state of the land, and the aqueous agencies upon it. In some instances at present, and it is to be expected that hereafter many more will be established, the relative epochs of certain terrestrial, lacustrine, and marine phenomena may be determined, but it is not the less certain that these phenomena belong to three independent series, which must be studied apart before they can be understood together.

It must be evident from what has been said before that a considerable proportion of the old strata had at the commencement of the tertiary system been raised above the sea, some parts by violent, others by gentle and continued elevation. In the latter way, we imagine, the chalk and oolites of England to have been a little raised above the sea at this period, so as to leave broad planes of the chalk rising gradually from the sea, and, of course, exposed to the violence of its shores, and other parts dry and fit for the growth of plants and the residence of animals. In France the same effects may be supposed to have happened round the greater part of the basin of Paris, while the old granitic rocks of central France, had sometime before raised themselves to nearly their present altitude, and constituted a shore for the oolites and the chalk. The mountains of Brittany, the chains of the Cevennes, the Jura, and the Vosges were also conspicuous in France, while the Black Forest, Odenwald, Harz, Erzgebirge, and Bohemian mountains generally had assumed their present relative heights. Also all the primary tracts of Britain, Scandinavia, Finland, and the Ural had long since circumscribed the ancient sea, or basin of Europe. But as yet the Pyrenees and Apennines, the Alps and Carpathians, had been only partially raised from the deep sea, though enough it would appear to divide the ocean into limited seas, gulfs, and bays, in which the tertiary strata were to be deposited.

This brief sketch will convey a tolerable notion of the observed extent of the tertiary deposits in Europe. The Eastern and South-Eastern parts of England, a large tract round Paris, another equally large area in the South-West of France, detached deposits in the Loire and the Allier, the valley of the Rhone, the valley of the Rhine from Basle to Mayence; the great hollow between the Jura and the Alps, the plains of the Danube and the Po, the subapennine region, many points in Southern Spain, the central basin of Bohemia, these are the tracts at present best known, but they are not the most extensive. From the Ardennes, Harz, Riesengebirge, Carpathians, and Caucasians, great part of the space North-Eastward to the primary rocks of the Oural and Finland is composed of a variable mass of tertiary rocks resting on secondary and primary formations. The Eastern coasts of North America, large areas in Northern Africa and in the region South of the Himalaya, are covered by tertiary rocks.

As far as appears at present, the marine parts of these deposits were formed beneath waters, some of which were connected with the German Ocean, as the Eastern parts of England, the Northern parts of Germany, &c., others with the English Channel and the Atlantic Ocean, as the South of England, Paris, Bourdeaux, and the remainder branched off from the Mediterranean, the Black Sea, the Sea of Azof, the Caspian, &c.

As in the present day the molluscous productions of one sea are distinguishable from those of another, by differing according to latitude and local circumstances, according to the nature of the coasts, influx of rivers, and many other causes, so we may expect the case to have been formerly. This is found to be the fact. The tertiary strata have several common and characteristic features, but they show differences of great importance, both mineralogical and organic, which clearly indicate the difference of circumstances of their production.

We shall first describe the English tertiaries, distinguishing them as marine and lacustrine, and we shall afterwards present a comparative view of the most remarkable contemporaneous foreign deposits.

Tertiary System of England.

The following is a Tabular view of the series of these deposits in England.

		Feet.
Upper marine formation.	Crag, a local marine deposit, consisting of two parts; one a coarse, calcareous, zoophytic, and shelly rock, the other a loose deposit of sand, pebbles, and shells	30 or 40
Lacustrine deposits.....	Enclosing between them an intervening layer of marine, or marino-lacustrine shells, &c.	
Lower marine formation.	Bagshot sand. London clay, with septaria rich in shells. Plastic clay group, consisting of marl covering the chalk, coloured clays, lignites, pebbles, and sand, with shells.	300 to 600

We must here observe, that in the preceding Table there is probably a hiatus between the London clay and the lacustrine deposits in Hampshire, that there is no case where the crag overlies the fresh-water beds, they being found only in separate districts, and that it is also probable that a hiatus exists between the London clay and the crag. Notwithstanding the want of direct sections, comparisons with the tertiary strata of other districts appear to warrant us in classing the crag as a more recent deposit than the lacustrine beds. This will appear in the sequel.

The Lower Marine Formation

consists of two principal groups which are in many cases very distinctly characterised, and always appear to indicate considerable difference in the state of the waters which produced them.

The *plastic clay* group consists, generally, of green, yellow, and white sands, with or without marine shells, layers of rolled flints, occasionally furnishing attachment to oysters, clays and marls of a yellowish or bluish colour with shells, and sometimes of many various tints, and then mostly devoid of shells. Beds of lignite also occur in the sands of this group.

The Map will show with sufficient accuracy the general range of this group from Essex through Buckinghamshire to Reading and Hungerford, and on the North side of the Kingsclere ridge of chalk, to Guildford and Croydon, and through Kent to Chatham, Canterbury, and Deal. South of the Kingsclere and Wealden ridge it ranges above the chalk from Newhaven and Brighton by Chichester near to Arundel and Houghton Hill, and thence to Dorchester, including the pipe-clay of Poole Heath, and turning Eastward again forms a narrow ridge of vertical strata between the chalk and London clay of the Isle of Wight.

The sections of the plastic clay group are usually considered to be very irregular and confused, and so, indeed, they are, and mark, upon the whole, a turbulent period and varying velocities of water. But we believe it possible to arrange these varying sections so as to present a tolerably consistent Tabular view thus·

Plastic clay group.	Upper part, consisting of coloured sands and coloured clays with beds of lignite, and occasional layers of flints.

Plastic clay group. Middle part consisting of blue clay, or marl, with cerithia and other shells, sometimes alternating with sands, with or without shells.

Lower part containing green sands often associated with flints and pebbles, and occasionally full of oyster shells, sharks' teeth, &c.

The following section of Loam Pit Hill, near Lewisham in Kent, by Dr. Buckland, will serve to convey a good notion of the general characters of the plastic clay group near London, except that the quantity of rolled pebbles is smaller than usual.

London Clay above.

	Feet.
Alluvium	
Striped sand, yellow, fine, and iron-shot	10
Striped loam and plastic clay, containing a few pyritical casts of shells, and some thin leaves of carbonaceous matter	10
Yellow sand	3
Lead-coloured clay containing impressions of leaves	2
Brownish clay containg cytheræ, estimated at	6
Three thin beds of clay, of which the upper and lower contain cythereæ and the middle oysters	3
Loam and sand, in its upper part cream-coloured, and containing nodules of friable marl, in its lower part sandy and iron-shot	4
Bed of ferruginous sand containing flint pebbles	12
Coarse green sand, containing pebbles	5
Ash-coloured sand, slightly micaceous, without pebbles or shells	35
Green sand identical with the Reading oyster beds, containing green-coated chalk flints but no organic remains	1
Chalk with beds and nodules of black flint	

The green sandy lower part of the group, with or without pebbles, oysters, and other shells, and sharks' teeth, appears to be constant and very characteristic, being found at Sudbury, Reading, Woolwich, &c.; and also occurring in the Isle of Wight.

The blue shelly clays of the middle part are well developed and rich in fossils, (much analogous to those of the London clay,) about Woolwich and other parts of Kent, and attain the monstrous thickness of 200 feet in the Isle of Wight, but they are not so continuous as the green sands. In the New Forest, and at Newhaven, they much resemble the Woolwich beds in their zoological contents.

The upper series of coloured sands, clays, and lignites, arrives at great importance in Hampshire, but is only feebly traceable around London, and appears quite unknown in Essex and Suffolk, and generally on the Northern rise of the chalk from the Vale of the Thames. The pipe clay of Poole in Dorsetshire, which is of white, grey, or blue colour, belongs to this division. It overlays a seam of friable lignite (brown coal) somewhat like Bovey coal.

There are several layers of white pipe clay at Poole Heath, three to five feet each, alternating with black sand, red sand, and brown clay, and covered by white sand. All along the North side of the range of chalk hills which extend from Handfast Point to beyond Corfe Castle, there is an extensive stratum of pipe clay in a horizontal position. It contains a bed of coal exactly resembling that of Alum Bay in the Isle of Wight. (Webster, in *Geology of England*, p. 53.)

The celebrated section of Alum Bay, for which we are indebted to Mr. Webster, exhibits the vertical beds of the plastic clay group of the astonishing thickness of more than 1000 feet.

The series here admits of the same general divisions mentioned above.

Upper part, consisting of 543 feet of highly coloured and variegated pipe clay, white, yellow, grey, and blackish, and alternating even minutely with beautifully coloured sands. Near the middle are three beds of lignite, in which fruits and vegetable reliquiæ are observable, and further to the North (nearer the top) are five other beds of the same sort of coal, each a foot thick, under this is a series of coloured and variegated sands 321 feet thick.

Middle part. Dark blue clay 200 feet thick enclosing much green earth, and nodules of a dark argillaceous limestone with shells. (Cytheræa, &c.)

Lower part. Green, red, and yellow sand, 60 feet.

The London Clay

Extent and characters.

is a very simple argillaceous deposit, of considerable but variable thickness, in one place (Wimbledon) exceeding even 530 feet, and in another (High Beech in Essex) 700 feet. It is usually of a lead-grey, or blue colour, but dull brown and red clays occur in it, perhaps most usually in the lower part. Green grains are often observable in it, a few sandy layers occur, and these, usually containing green sand, are indurated at Bognor and Selsea into a considerable rock. Septaria abound in it, and some imperfect laminæ of marly limestone have been noticed. It lies upon the plastic clay group over considerable tracts in Essex, Berks, Hertfordshire, Middlesex, Hampshire, Surrey, and Kent, on the Northern side of the Wealden ridge, borders the Southern coast from Worthing to Hordwell, and separates the coloured sands and clays of the Isle of Wight from the fresh-water deposits above. It is chiefly interesting for the vast number, beauty, and variety of its organic remains, of which the cliffs at Harwich, Sheppey Isle, Hordwell, Stubbington, &c. are rich repositories. Considerable quantities were also obtained in cutting for the Archway at Highgate.

Having been much exposed to watery action, which it could ill resist, it is often left in insulated hills, upon the substrata of sands and clays. Mineral springs, so common to blue clays, rise in considerable number from the London clay near the metropolis. The most remarkable are those of Epsom, famous for their sulphate of magnesia, Bagnige Wells, and Acton.

It yields little water to the well-sinker, but on being pierced to the sands below, or, as circumstances may require, to the chalk, great streams of water rush up, and may even overflow the surface if the chalk hills which gather and transmit the water be sufficiently elevated. This is the case about London, under which subterranean streams flow from the chalk of Surrey on one side, and that of Hertfordshire on the other.

The London clay possesses all the characters of a very quiet and continuous deposit, perhaps in deep water, yet not far from shore, since a few considerable remains of land and littoral productions occur in it, as wood, turtles, and crocodiles, but no pebbles nor coarse sands.

The temporary turbulence of the plastic clay period had wholly passed away, and only finer sediment in great quantities found its way to the sea. Shells of the most delicate and fragile forms are perfectly uninjured in this clay, except in the rare case of its being laminated.

Bagshot Sand.

We shall place the Bagshot sand described by Mr. Warburton (*Geological Transactions*) above the London clay, on which it rests in the only districts in which as yet it as been much noticed. Bagshot Heath and Hampstead are the principal localities. Its fossils are few and imperfect, but are thought by Mr. Warburton to resemble some of those found in the upper marine formation of the Paris basin.

Fresh-water Group.

Isle of Wight.

For our knowledge of the fresh-water tertiary strata of England, we are indebted to Mr. Webster. They exist only along the Northern side of the Isle of Wight, and on the opposite coast of Hampshire. After the chalk and older strata, together with the plastic clay and sands and the London clay of the Isle of Wight, were thrown by convulsive movements into positions so extraordinary, the fresh-water strata now to be described were deposited horizontally over the line of this great disturbance. What *interval of time* may have elapsed, or what intermediate Geological phenomena may have occurred between the dislocation of the chalk and marine tertiaries, and the formation of the fresh-water deposits above, cannot be discovered, at least in this situation. It is in the highest degree probable, that very tumultuous deposits must have succeeded the convulsive movements, and it is quite possible that under the fresh-water deposits of Headen Hill others may exist, which, if marine, might render more complete than it is the English series of marine tertiaries.

The fresh-water strata of the Isle of Wight are parted into two minor groups by an intermediate set of layers of light green marl, 36 feet in thickness, containing in extraordinary abundance and great perfection marine shells of the genera potamidum, voluta, fusus, natica, ancilla, cyclas, venus, cytherea, ostrea, &c. These are distinct from the fossils of the London clay. Some species in this bed are decidedly fresh-water mollusca, as neritina-like fluviatilis, and melanopsis. Potamida, which are numerous, appear to indicate an estuary deposit; and it is probable that we may be justified in regarding the whole of this, which is called the upper marine of the Isle of Wight, as a local estuary deposit, caused by some temporary physical change in the region between the eras of the two decidedly lacustrine groups, which it separates.

Crag.

Range and characters.

The most recent of all the marine stratified deposits, is also one of the most irregular. It occurs only in the Eastern part of England over a narrow space of little elevation from the cliffs of Walton in Essex to beyond Aldborough in Suffolk. It is also known to some extent in Norfolk, particularly at Bramerton near Norwich.

In this short course the crag is found to rest on the London clay at Walton and Bawdsey, and on chalk at Bramerton, being evidently a much later deposit than either and wholly independent of them. It exhibits also considerable variation of character. Its general aspect in numerous pits in Suffolk is a ferruginous mass of shells, dark pebbles, and bones and teeth of fishes and reptiles, mixed up in a confused mass of sand, sometimes grouped into beds, and sometimes exhibiting oblique and disordered laminæ, very much resembling the general, character of a modern very shelly beach. And from the manner in which it lies in the country about Ipswich and at Bramerton, there can be little doubt that it is really an ancient beach of the German Ocean. But about Aldborough and Orford the crag assumes a totally different character, becoming, in fact, a zoophytic limestone, an accretionary rock, formed by the cementation of coralline reliquiæ, shells, and calcareous sand, probably after the manner of the Guadaloupe accretionary limestone, and a similar littoral formation on the coast of the Isle of Ascension. This coralline limestone contains some of the most characteristic shells of the ordinary crag, and is clearly of the same era as that heterogeneous deposit.

Shells of the Crag.

The quantity of shells contained in the ordinary pebbly crag of Suffolk is beyond all calculation. The name of crag is, we believe, derived from a British word signifying shell, and the Suffolk pits have been for a long time in work solely to manure the ground with their calcareous exuviæ. The number of species here buried is also very great. Upon comparing them with recent kinds we are presented with very curious and striking results. There are several of the crag shells so exceedingly similar to recent shells of the German Ocean, that it is impossible to distinguish them. Turbo littoreus retains its colour, many others are with difficulty separated by minute discrimination; but some, as the corals of Orford, pecten princeps, terebratula Dalei, and others, are evidently unlike any thing now existing in the German Ocean, and indeed not now to be paralleled in any part of the World. A small number of the crag shells appear very similar to some in the London clay, but in general they have few common analogies, and the most cursory observer must be struck by the total difference of general aspect. The London clay shells recall to our memory the shores of a *Tropical climate*, the crag fossils speak to us of an ancient race of shells of *our own seas*. But the corals are *sui generis*, and upon the whole, those Geologists who are most desirous of uniting the crag deposit to the present system of Nature, must acknowledge that it bears the stamp of an ancient and peculiar era. It has often been stated, that bones of elephant, teeth of mastodon, &c. have been found in the crag. This mistake, as we believe it to be, may have arisen partly from the notion once prevalent, that crag was only a particular kind of diluvial deposit, and partly from attempting to *supply an omission* in Mr. Smith's Work, (*Strata identified*,) in which the tooth of a mastodon is figured from a noble specimen now, with this original collection, deposited in the British Museum, but without mention of locality. It was picked up under the diluvial cliff at Happisburgh, from which so many elephantoidal teeth and bones have fallen into the sea. A very unexpected addition to the list of organic remains of the crag, is the badger, (probably undistinguishable from the common European species,) of which good specimens of the skull and leg bones are in the Yorkshire Museum.

It must evidently be of little use to give sections of such a deposit as the ordinary crag. We shall therefore subjoin only Mr. R. Taylor's account of the Bramerton pit, and mention that, in general its thickness is about 30 feet, and its greatest height above the sea, in Walton Naze, 50 or 60 feet.

	Feet.
1. Sand without organic remains	5 .
2. Gravel	1
3. Loamy earth	4
4. Red ferruginous sand, containing occasionally hollow ochreous nodules	1¼
5. Coarse white sand, with a vast number of *crag shells*	1½

	Feet.
6. Gravel with fragments of shells	1½
7. Brown sand, in which is a seam of minute fragments of shells 6 inches thick	15
8. Coarse white sand with *crag shells*, similar to No. 5. tellinæ and murices most abundant	3½
9. Red sand, without organic remains	15
10. Loamy earth, with large stones and *crag shells*	1
Total	49
Large irregular black flints crowded together *in situ* in the chalk. Attached to these flints are echini, terebratulæ, inocerami, and belemnites	1
Chalk to the bed of the river	15

Foreign Tertiary System.

Under what circumstances deposited.

The disturbances which preceded the deposit of the whole or the greater part of the tertiary strata, were very extensive, and appear to have operated considerable changes in the configuration of the land, and to have left the European seas, certainly expanded much beyond their present limits, but yet pretty evidently related to the present depths of the Atlantic, Baltic, and Mediterranean. It has long been the custom to speak of tertiary strata as being particularly deposited in *basins*; an inaccurate use of this term, for the tertiary strata are not more, nor perhaps so much, separated into basins as many of the older strata. We recognise, indeed, in them a greater local diversity, such as at present obtains, both with respect to the materials deposited and the organic remains entombed, in separate branches of the same sea, or at distant and dissimilar parts of the same coast. The true way of considering the tertiary strata is, to view them as the varied deposits of one long period, produced chiefly in branches of one great ocean, variously divided by the elevated lands. Some particular deposits may perhaps be best explained by allowing the existence of mediterranean seas, or even salt-water lakes. Cases in which fresh-water and marine shells alternate must be examined upon their own evidence, to learn whether such alternations were produced in a lake, or at an estuary; and finally, the true fresh-water strata of the tertiary period must be separately treated, having such relations to the marine tertiary accumulations as the fresh-water formations of the present day have to the deposits now in progress below the sea. Thus we shall have purely marine strata, marino-fluviatile, or marino-lacustrine strata, and lacustrine strata, all referable to the tertiary period, the relative eras of which can sometimes be correctly *determined*, sometimes satisfactorily *inferred*, and in other cases only *conjectured*.

The relative age of strata which were deposited in the same branch of the sea, can be *determined* by observation, even though subsequent convulsions may since have separated the deposit into detached portions, as for instance the Hampshire and the London marine tertiaries. It can be *inferred* satisfactorily, even for originally distant deposits, when large suites of organic remains, not differing more than we may expect to happen in such cases, concur with a general analogy of Geological position; and in this case, the inference is the stronger, if the data analyzed and referred in portions to successive periods, apply in a similar manner to the two localities.

The mineralogical character of the deposits is of importance in proportion as the deposits happened in the same branch of the sea, along the same line of coast, parallel to the same range of mountains, or to similar ranges of analogous rocks. In short, tertiary strata may be expected to show close agreement, considerable resemblance or general analogy, according to the local circumstances of their production, and it is perfectly consistent with Geological experience and sound theory, that the clay of London, the calcaire grossier of Paris, and the lower subapennine marls, may be exactly contemporaneous deposits, deriving their peculiar character from the peculiar circumstances of their localities. If we do not so often find in the older systems of strata these great mineralogical contrasts between exactly contemporaneous strata, we must remember that the circumstances of land and sea, when the earlier deposits happened, were more uniform, and that by a long succession of convulsions the tertiary sea was made to flow round islands and promontories, containing a vast variety of rocks, reared in deep or shallow waters, and exposed in various degrees to the processes of disintegration.

We may venture by the aid of what is known of the effect of former convulsions, and the help of the characters furnished by the newer strata, to describe the hydrography of the great European Sea in which tertiary strata were accumulated.

Extent of the tertiary Sea of Europe, &c.

It may perhaps be described as an immense inland sea, bounded on the West by a broken line of elevated land in Spain, Auvergne, Brittany, England, Scotland; on the North by the Scandinavian peninsula, Finland; on the East by part of Russia, the Oural, the mountain circle which encloses the Aral, the Caspian and the Black Sea, and a line prolonged through Syria toward the Red Sea; on the South by a line including the present Mediterranean, part of the Libyan Sands, and Egypt. This ancient Mediterranean appears to have been connected with the Bay of Biscay and the Atlantic by shallow channels between Angers and Poitiers, and by the line of the Canal of Languedoc. It embraced the North Sea, and so probably communicated with the Northern Ocean, included a part of the Baltic, and was open to the Indian Ocean through the Red Sea.

In this vast area rose at that time irregular tracts of land, forming upon the whole two islands. The Northern island, stretching in a sweep from the Cevennes to the Carpathians, and including the great plateau of central France, the Jura, Vosges, Schwartzwald, Ardennes, Taunus, Westerwald, Teutoburger Wald, Hartz, Erzgebirge, the circle of Bohemian and Moravian mountains, and the long range of the Carpathians. In the Southern island, rose in partial peaks, and with small surface, the Alps of that epoch, connecting themselves with the Apennines and the mountains of Dalmatia, Croatia, and Greece. The ancient Sea of Bohemia and the Sea of the Rheinland were entirely or nearly surrounded by land; the Seas of Swisserland and Hungary expanded into the Black Sea, and contracted their waters into a narrow channel along the line of the Rhone, there to unite with the Mediterranean; and the basin of Paris appears to have been only partially connected by shallow channels with the North Sea or the Bay of Biscay.

Its relation to the existing Seas.

Viewed then in connection with existing Seas, we may consider the inland tertiary Sea in several portions.

1. The arms and branches of the Mediterranean, stretching up the extended Gulf of Lyons, the Sea of Swisserland and Hungary and the extended Adriatic Gulf, washing the Eastern part of Spain, Libya, and Egypt, and joining the Red Sea.
2. The dependencies of the Atlantic and North Sea, as the Bourdeaux basin, which was also connected with the Mediterranean, the basin of Paris, the great Sea of England, and the Netherlands. To these may be joined the area of Northern Germany, Russia, and the Countries bordering on the Black

Sea and the Caspian. We might perhaps be justified in making a separate division for the latter surfaces, could we appeal to any satisfactory account of the organic reliquiæ of Countries which as yet are very imperfectly known.

For comparison with the English series, we shall first take the example afforded by the basin of Paris, so admirably described by Brongniart and Cuvier, and on that account frequently appealed to as the general type of tertiary formations.

Following the general classification of Messrs Brongniart and Cuvier, we shall divide the Parisian marino-lacustrine strata into five groups, in the order of their eras.

5. Upper fresh-water or epilimnic group.
4. Upper marine (sands and marls.)
3. Lower fresh-water or palæotherian group.
2. Lower marine (calcaire grossier.)
1. Plastic clay group, lately subdivided by M. Brongniart into three groups. (*Tableau des Terrains.*)

Plastic c gr

Our remarks on these deposits will be as concise as the great interest attached to a right understanding of the mode of their formation will allow. The idea we formed to ourselves from a consideration of the plastic clay group of England, was that of a varied series of deposits, consequent upon some considerable convulsions, partly derived from the waste of the cretaceous system, and accumulated in a sort of estuary of that system. Pebbles and sands, with or without shells in confusion, a few bands of clay with shells, and beds of lignite, layers of pipe clay, and plastic clay, lying in sand, compose the rather heterogeneous group, which ends upwards with the abundant tranquil deposit of London clay.

On the great scale, the plastic clay group of the basin of Paris presents very analogous characters. It rests on the irregular and worn surface of the chalk, contains accumulations of pebbles, beds of lignite, layers of coloured plastic clay, and by occasionally including beds of calcaire grossier, analogous to the shelly layers of the English group, appears to leave hardly any important point of resemblance unsatisfied. On a careful review, however, some differences arise. The order of succession of the several parts is not exactly similar. The French series taken generally may be thus expressed:

Upper part consisting of potter's clay, marls, sands, and much lignite, the clay containing many lacustrine shells, as cyrenæ and melanopsides, alternating with a few marine shells, as ostreæ and cerithiæ; the lignites containing remains of mammalia and fresh-water reptiles.

Middle part or plastic clay and sands, sometimes alternating, the former generally beneath, of very uncertain thickness, indistinctly stratified and devoid of shells.

Lower part very local, consisting of fragments of chalk, flints, &c.

These deposits are very unequally spread in the basin of Paris, and the lignite with shelly clays and marls belongs principally to the vicinity of Soissons. We may draw the following inferences. (1.) That the convulsive movements which wasted the chalk of England, and raised its originally deep strata to a littoral and estuary situation, were also experienced in the basin of Paris. (2.) That in this estuary irregular deposits happened, both marine and fresh water, the latter prevailing in particular places more than in the corresponding basins of England, and recognised by distinct layers of fluviatile mollusca, sometimes alternating with deposits containing a few marine shells. The basin of Paris seems therefore to have been at first an estuary, admitting into it considerable currents of fresh water from rivers or lakes, containing shells, crocodiles, and turtles, and transporting vegetables; but the deposits were generally more tranquil than the contemporaneous products of England.

The "*lower marine*" *group*, or calcaire grossier, and its coeval and associated sandstones, form the principal and characteristic rock of the Paris basin, in which the vast number of marine shells occur. The calcaire grossier is a granular, sedimentary, sandy, yellowish-white limestone, of considerable thickness, regularly bedded and jointed, with partings of a marly nature, including occasional beds of sand, and in some cases lignite and marls. The lowest part of the rock is usually filled with green silicate of iron, and can hardly be distinguished from some kinds of marly green sand. It contains hardly the least trace of metallic substances, but encloses a few beds of hornstone, some cubic fluor, quartz, and calcareous spar. It is the building stone of Paris. In some parts, it is replaced by a developement of sandy beds, which often exhibit glistening fractures. Pebbles lie in it, chiefly at the top and the bottom. Upwards of 1500 species of marine shells belong to this group, and only a very few land or fresh-water species, rarely brought down with vegetables, diversify the character of the deposit. A great proportion of the shells of the London clay are recognised among the more numerous reliquiæ of the Paris basin.

The lignite and marls occasionally included near the top of the calcaire grossier, (Brongniart,) remind us that the action of the fresh waters, though nearly unobserved during this long period of the deposition of the calcaire grossier in quiet sea, might easily be recalled to the basin of Paris by a change of local circumstances.

Such a change occurring, a part of the basin of Paris was surrendered for a time to the undisputed possession of fresh water, and the following group was deposited.

Palæotherian or lower fresh-water group.

The palæotherian, or lower fresh-water group, is principally, says M. Brongniart, a chemical deposit from water, or at least this mode of origin is very frequently to be traced in it. Coarse mechanical aggregates, the result of violent currents, are unknown in it; while gypsum, siliceous nodules, and agates are frequent, and sulphate of strontita, carbonate of lime, and silicate of magnesia occur in the marls which compose a large part of the mass of the formation. But it is from the remains of terrestrial and fresh-water plants, and the exuviæ of land and fresh-water animals, that this group of strata receives its most exact as well as most interesting characters. In the interior of its mass no marine bodies of any kind have been found, but several plants and shells of the land and fresh water, generically identical with existing tribes, as well as land quadrupeds belonging to genera now extinct. The study of these quadrupeds, first awakened in Cuvier that indefatigable zeal in the examination of fossil animals, which has established the permanent union of the highest branches of Geology and Zoology.

Argillaceous and calcareous marls with limnææ, frequently alternating in very thin laminæ, (a common character of lacustrine deposits of all ages,) constitute the mass of this palæotherian group; gypsum in broad crystallized masses, of a vertically prismatic structure, not stratified, is frequently associated with them, as in the basin of Paris, at Puy en Velay, and at Aix en Provence, silicious limestone locally diversifies them, and yields agates, menilites, nectic quartz, &c. To this group M. Brongniart also refers the lignites which lie in the molasse of Swisserland. The quadrupedal reliquiæ are, perhaps exclusively, found in the gypsum, and few other organic bodies accompany them.

---

* Mr. Chantrey, whose unrivalled eminence in his profession is united with very extensive and accurate information on other subjects, has observed in the interior of plaster casts of large statues, which had been subjected to a drying heat of 350°, an irregularly prismatic structure, comparable to that of the gypsum of Montmartre.

This evidently fresh-water group occurs in many parts of France, sometimes, as in Auvergne and Cantal, without the least trace of a genuine marine tertiary basis. About Montpellier it is found in combination with marine deposits nearly as in the Paris basin, and there appears good reason to believe that the causes which repelled the sea from that basin were extensively at work in other parts of Europe. This indeed is not a very difficult part of the problem. The expulsion of the sea may easily be imagined to have happened by the elevation of new land, or by a great local dislocation, such as we know to have often occurred; and thus a fresh-water deposit in the basin of Paris might be laid on a basis of immediately antecedent marine tertiary strata, at the same epoch that in other parts of France elevated above the sea before the tertiary period, these deposits were laid on any of the older rocks. From the estuary or lake which we now call the basin of Paris, to the mountains of Auvergne, there might be formed, contemporaneously, (that is, in a given Geological period,) many fresh-water deposits of varying character, under varying conditions, which are to be ascertained by special investigation of each case. But after the completion of this lower fresh-water deposit, subterranean movements brought back the sea into the basins of Paris and Montpellier, at the same time that marine exuviæ were introduced into the basin of Hampshire. It does not follow, as a necessary inference from the data before us, that this subterranean movement was centred below the basins of Paris, Montpellier, and Hampshire, nor that these basins were raised or lowered at all; it is only certain that subterranean movements must have occurred in such a manner as to interrupt and restore at intervals the connection of these districts with the ancient sea. In what respect is this different from the case of the Weald of Sussex and the ancient coal basin of Yorkshire?

Upper marine group.

The "*upper marine*" *group*, produced in the basin of Paris by the marine irruption which covered the palæotherian gypseous marls, is composed chiefly of sands of many colours, occasionally indurated to stone, with fewer shells than in the lower marine group. The base of the group is, at Montmartre, a mass of calcareo-argillaceous marls, greatly analogous to those of the fresh-water group below, a gradation of character very much to be expected; conglomerates lie on the coloured sands in the Northern and Eastern parts of the Paris basin. A sandy, shelly limestone containing bones of the palæotherian, and also of the subsequent diluvian era, called *calcaire moellon* by M. de Serres, abounds at Montpellier and Narbonne. The molasse of Swisserland, a very complex and disturbed deposit, is referred to this era.

Upper fresh-water group (Epilimnic) group.

The parallel between the three basins of Hampshire, Paris, and the South of France, is drawn still closer by the occurrence in all three of "upper fresh-water" beds, the last usually included in the tertiary strata. It must in some cases be doubtful whether the upper fresh-water deposit recognised in a tertiary district be of the antiquity of this Parisian epilimnic group, and it is highly probable that lacustrine deposits will be found of all intermediate ages from the date of the uppermost tertiaries of the Paris basin to the deposits of the modern era. Such, perhaps, are the lacustrine groups of Œningen and Georgesgemund, which have become better known to the English reader in consequence of Mr. Murchison's descriptions. But, in the case of the localities mentioned above, this doubt is not to be entertained. The most characteristic rock of this group in the basin of Paris is the millstone, a silicious rock full of cells and tubular sinuosities, attributed to the extrication of gas from the bed of the lake, as is known to happen in ordinary cases, and some fresh-water shells and seeds of chara. (Gyrogonites.) In other districts, especially in Italy, a marly limestone, analogous to the travertino which is daily formed there by carbonated springs, is considered by Brongniart the representative of this group, but it is obvious that this tufaceous deposit may be of all ages. The upper fresh-water deposit, with, probably, other recent deposits of the same nature, is recognised in Auvergne and Cantal, on the Loire, Allier, and Cher, in the Department of Gard, in Swisserland, Austria, and Hungary.

Faluns of Touraine.

To these characters of the strata in the Paris basin, described by MM. Brongniart and Cuvier, must be added a notice of a set of gravelly sands in the Faluns of Touraine, long celebrated for abundance of shells and other organic remains, but which were first examined with attention by M. J. Desnoyers. Along the line of the Loire valley at several points, as well as at Rennes, shelly and gravelly deposits occur, which, from Desnoyers's investigation, appear certainly to be of posterior date to the whole Parisian formation, and to contain not only a variety of shells and corals distinct for the most part from those of the Parisian tertiaries, but also a mixture of quadrupedal remains, both of the palæotherian and mastozootic era. Besides palæotherium, lophiodon, and a species of anthracotherium, which would generally be referred to the era of lacustrine tertiaries, there are bones of mastodon, hippopotamus, rhinoceros, tapir, horse, and deer. These, the most recent, probably, of all the deposits connected with the Parisian series, are compared by M. Desnoyers with the English crag; but the propriety of this reference is denied by Mr. Lyell, on the ground that their suites of organic remains have not the same ratio of analogy to existing tribes; the resemblance of the deposits is, however, remarkable. Thus a sequence of tertiary deposits of the same general characters appears to be clearly ascertained in the Southern parts of England and the Northern parts of France, and the beds in the two localities are of the same, or nearly the same age. This series has three principal marine terms, of which the lower one (London clay in England, calcaire grossier in France) is very continuous and the most important, the middle one is variable, and the upper one local and littoral, perhaps, we may add, of rather uncertain date. The series contains also two lacustrine terms, and one, the lowest of all, a product of transient convulsions consequent on the rise of the chalk strata.

This agreement is very interesting. Yet it is not to be thought that in other parts of Europe, which are not subjected to the same repeated convulsions, a similar sequence of marine with similar interpolations of lacustrine deposits should often be met with. On the contrary, it ought to be expected that when the tertiary deposits are wholly marine, the triple character, which in France and England they derive from definite periods of convulsion, should be confounded into a general series of many graduated or alternating terms, as happens to the oolitic and other extended marine systems. The further descriptions of tertiary strata, introduced for comparison with those of England, will be divided into marine and lacustrine; the former will be first noticed.

South of France

The tertiary strata of the South of France are generally coeval with those of Paris, and the greatest assemblage of shells and other marine remains lies in sandy and subcalcareous beds, thought by M. Brongniart to be of the same age as the interlacustrine sands of Paris. In the districts of Bourdeaux and Dax, 600 species of shells have been collected from these strata, which Mr. Lyell (vol. iii) arranges in four divisions thus:—

4. Siliceous sand without shells.
3. Gravel.
2. Sand and marl with shells.
1. Blue marl with shells, sometimes 200 feet thick.
Below all these calcareous strata occur with shells of the Paris basin.

M. de Serres has shown the much greater accordance which the Bourdeaux and Montpellier shells bear to those of the subapennine formation of Italy than to the strata of the basin of Paris, and it is from comparison of the organic remains that Mr. Lyell ranks together the Bourdeaux and Touraine shells, and puts them above all the Parisian beds. It is desirable to attain an accordance of opinion in the relative age of these strata, because they furnish common ground of comparison for the deposits which border the Apennines, the Alps, and the Carpathians.

North of the Alps.

The most complete section of tertiary strata along the Alps has been furnished by the researches of Murchison and Sedgwick in Lower Styria.

Uppermost group, calcareo-arenaceous.	Calcareous sands and pebble beds, calcareous grits and oolitic limestones, containing many shells, some of these of existing species.
	White and blue marl, calcareous grit, white marlstone, and concretionary white limestone with shells.
Middle group, calcareous.	Below this is a coralline limestone, with shells, in one place 400 feet thick, associated with marls
Lowest group observed.	Conglomerate with micaceo-calcareous sand, and millstone conglomerate.
	Blue marly shale and sand, with shells analogous to those of the calcaire grossier and London clay.
	Shale and sandstone with beds of lignite, accompanied by fluviatile and terrestrial exuviæ.
	Conglomerates, grits, and micaceous sandstones.

The coralline limestone here mentioned serves as a good line to connect the sections along the line of the Carpathians. At Vienna, Murchison and Sedgwick give the following series:—

Alluvial beds? of löss and gravel, the latter containing bones of mastodon, tapir, anthracotherium, &c.
Fresh-water limestone.
Leithakalk or coralline limestone and calcareous conglomerate.

Lower group	Upper blue marls and sands, very rich in shells, yellow sand and shells.
	Lower blue marls 300 feet, compared to London clay.

Transylvania, &c.

In Transylvania, Boué gives the series thus:—

Upper group shelly sands, marine and fresh water.
Sandy coarse limestone, equivalent of the Leithakalk.
Molasse.
Clay and marls blue and yellow.

And this applies to Moravia and the West of Hungary, where the lower beds are inclined toward the Carpathians.

Gosau beds.

Below all these tertiary strata, in Geological position, but raised to a great height in the Alpine region by powerful dislocations, occur those shelly marls and sands with conglomerates and traces of lignite, which have acquired celebrity from the researches of Murchison, Sedgwick, Boué, Von Lilienbach, and other Geologists. The discussions on their relative age are yet unsettled, because no sections can be obtained, under the difficult circumstances of the case, which put in a clear order of uninterrupted succession the whole mass of tertiaries, or allow a very confident deduction concerning the relation of all the parts taken separately. The obscurity of the subject is increased by the admitted indistinctness and variation of mineralogical character in the tertiary sands and conglomerates of the plains of the Danube. Yet it is not to be supposed that no inferences can be grounded on the laborious investigations of the eminent Geologists above named. The Gosau shelly beds are limited below by the Alpine limestone at Gosau, and in the Rentersberg by the same limestone, (hippuritic,) covered by grey or reddish marls and marlstone containing a few fossils of the chalk formation: above, these beds are known to pass under the molasses of the plains North of the Alps. Two sections, derived from the labours of Murchison and Sedgwick, will, with this understanding, sufficiently show the nature of the beds. The first is across the Valley of Gosau.

Uppermost group.	Red and green slaty micaceous sandstone several hundred feet thick. (Cap of the Horn.)
Second group	Green micaceous gritty sandstone, extensively quarried as whetstone, succeeded by yellowish sandy marls. (In the Ressenberg.)
Third group	Vast shelly series of blue marls, alternating with compact limestone and calcareous grit; traces of vegetables above, abundance of shells and corals in the middle and lower part. (In the Valley of Gosau.)
Lowest group.....	The above series gradually changes to beds of a more conglomerate character, which pass into red sandstone and marl containing gypsum; a coarse conglomerate, forming the base of the whole system, rests upon and *abuts against* the Alpine limestone. (Russbach.)

The discontinuity between the lowest part of this section and the top of the Alpine limestone is partially remedied in the Untersberg, where a series of four terms likewise appears.

Uppermost group.	A great succession of alternating masses of bluish micaceous marl, slate, clay, sandstone, and conglomerate. Some of these marls contain beds of gypsum and fossils resembling the suite of Gosau.
Second group	Beds of blue micaceous slate clay, and greenish micaceous sandstone.
Third group......	Sandy micaceous marls, alternating with conglomerates, and micaceous calc grit with nummulites. Subordinate to this system are red and variegated marls with gypsum.
Lowest group	A great deposit of marl and marlstone, generally of a grey but in some places of a red colour; containing a few fossils resembling those of the chalk formation.

These beds are conformed in declination to the Alpine limestones of the Untersberg.

Age of the Gosau beds.

The question lately discussed respects the age of these Gosau beds. Messrs. Murchison and Sedgwick conceive them to be the lowest of the tertiary series of the Country, and to have so much analogy to the system below as to be properly regarded as one of the connecting links of the cretaceous and tertiary rocks. M. Boué ranks them with the green sand system. On appealing to the organic remains, we learn that the affinity of *genera*, and the proportion of univalves and bivalves, bring the Gosau beds to a tertiary type; an examination of the *species* leads M. Deshayes to declare, (Lyell, vol. iii. p. 327.) that none of the Gosau shells are found in any recognised tertiary stratum, but that some of the most characteristic species of Gosau occur in the green sand below the chalk at Mons in Belgium. His researches have led him besides to the following decisive general statement, that no shell has yet been found which is common both to tertiary and secondary strata! Our own impression on the subject, derived from comparing the statements of those eminent writers who have enjoyed the fullest advantages of original examination, can be of no importance on either side; it will be more useful to set an example, unfortunately rare in such discussions, of deliberate indecision, and to appeal to future discoveries. Two remarks, however, must not be omitted. Though all the instances upon record should be found strictly to agree, (even when modified by further discoveries,) with that valuable and practical conclusion for which Geology is indebted to Deshayes, yet this conclusion is general, not universal, and cannot be employed to predicate the result of any new investigations. And again, though certain genera may not yet have been recognised among secondary strata, the deduction of the age of the Gosau beds from this source is of the same conditional character.

Molasse. The primary and secondary Swiss mountains are bordered on the North by a vast thickness of conglomerates, sands, calciferous grits, and lignites with mammiferous quadrupeds. These are referred by Brongniart to the interlacustrine marine beds of Paris, but the shells as yet found in it are few. M. Studer, of Berne, has amply described this immense and disturbed deposit.

Subapennine deposits. The subapennine strata are all that remain to be noticed in these comparative sections. No one since Brocchi has been more successful in the examination of these strata than Mr. Lyell, and they furnish much of the evidence which supports his classification of the tertiary system into eocene, meiocene, and pleiocene formations according to the degree of analogy which the organic fossils of those groups bear to existing races of marine animals.* They are of enormous thickness, (several thousand feet,) and must have required very long periods for their accumulation in the Mediterranean, from which they have been uplifted to considerable elevations on each side of the secondary Apennine ridges. The mass consists of innumerable alternations of calcareous and argillaceous marl, light brown, or blue, but the variation of mineral character is slight through the whole series, and not at all sufficient to furnish permanent marks of separation into groups. It is altogether like the sediment which we may suppose to be quietly deposited on the bed of the Mediterranean, by rivers which have left their coarser detritus inland. Beds of lignite are sometimes interstratified, as at Medesano near Parma; subordinate beds of gypsum interstratified with shelly marls and sand also occur in the Parmesan. Sandstone is also interstratified, and rarely compact limestone replaces a portion of the calcareous marls. The whole is covered in places, and unequally, by a coarse yellow sand and conglomerate, in which alternations of fluviatile and marine exuviæ are traceable, and other circumstances are observed which mark estuary or littoral action.

This may be taken as the character of the *middle* subapennine formation. The tertiary strata in the hill called the Superga, in Piedmont, have been described by M. Brongniart and other writers, and from personal examination with Mr. Murchison, Mr. Lyell has inferred that they are the *oldest* part of the tertiary system in Italy. Fine green sand and marl, and a subjacent conglomerate, (the boulders being of primary rocks,) compose these strata, which dip at the extreme angle of 70°, under the more horizontal bluish subapennine marls of the plains of the Tanaro.

Sicilian deposits. The most *recent* portion of the subapennine deposits is exemplified by Mr. Lyell in the tufaceous formations of Naples, the calcareous strata of Otranto, and probably the greater part of the tertiary beds of Calabria. But the most satisfactory view of the newest tertiary strata, is obtained in the Val di Noto, Sicily. Since Dr. Daubeny's account of that island, the phenomena of its stratified rocks have excited much attention, and Mr. Lyell has been eminently successful in deriving from them important inferences concerning the relative ages and periods of elevation of submarine strata. The following is an abstract of his descriptions.

The whole series of strata in the Val di Noto is divisible into three principal groups.

The uppermost group consists of limestone, sometimes 700 or 800 feet thick, often corresponding in mineral character with the calcaire grossier of Paris, but often more compact. It is regularly stratified and cavernous. These characters, however, are liable to vary in different parts of the island; near Noto it has the concretionary spheroidal structure of the form of the Italian travertino, and contains terrestrial vegetables. These strata prevail not only in the Val di Noto, but, as Dr. Daubeny stated, cap the hill of Castrogiovanni, 3000 feet above the strata. The organic remains of this limestone (generally casts) belong, with hardly any exception, to existing species.

The middle group, not abruptly distinguished from the upper one, consists of white calcareous sand, sometimes with a tendency to oolitic and pisolitic texture, such as the travertino of Tivoli; at Floridia near Syracuse, it changes to conglomerate with calcareous pebbles, associated with sandy limestone full of broken shells. In some parts of Sicily, this group seems to be represented by yellow sand, exactly resembling that superimposed in the blue subapennine marls of Italy.

The lowest of the three groups consists of an argillaceous deposit of variable thickness, called *creta* in Sicily. It resembles the blue marl of the subapennines, and encloses shells and corals in a beautiful state of preservation. The shells belong, with few exceptions, to recent species.

Other marly strata, probably tertiary, occur below, with gypsum, sulphur, and salt.

Relative Antiquity of Tertiary Deposits.

Sufficient data have now been stated concerning the local characters of tertiary deposits to show how variable are the strata of this series, and what great difficulties oppose themselves to a satisfactory classification of them according to their relative antiquity. The methods of inquiry which have been found so successful in the solution of that problem, when applied to secondary strata, are here much less applicable. The mineral character of these deposits is, far more than amongst secondary strata, dependent on the nature of the neighbouring mountains of older rocks, on the condition of the sea, and the state of elevation of the land. No two separate tertiary districts, unless perhaps those which follow the line of the Danube, could be satisfactorily compared by mineral characters alone.

---

* These terms are derived from *καινὸς*, (recent,) combined with *ἠὼς*, (the dawn,) *μείων*, (less,) and *πλείων*, (more.)

The thickness of the deposits is enormously unequal, and the angles of their inclination and their elevation above the sea afford no resting place in this research. Some help may ultimately arise from the theory of elevation of mountains; but M. de Beaumont's view, which alone seems to apply itself distinctly to this subject, is as yet too embarrassed with objections, and too little examined in detail, to be available.

al
gical

Nothing then remains on which to build hopes of arranging the tertiary series in a regular sequence according to their ages, but the evidence of their organic contents, and accordingly it is in this direction that the efforts of modern Geologists and Naturalists are vigorously exerted.

This being our only probable basis of operations, it will be well to examine its weak points beforehand, lest much labour be lavished on a fruitless undertaking. Difficulties of a very serious nature, and problems not yet solved, nor even entertained by Geologists, perplex the history of tertiary organic remains.

Mode of employing it in relation to older rocks.

Amongst the older rocks, notwithstanding the general admission of Mr. Smith's views, the organic remains have been chiefly used in reasonings on the condition of the land and sea at certain periods, defined, not by the existence of these organic remains, but by the occurrence of a given sequence of rocks, in which those remains are imbedded. It is true that the classification by superposition has been found wonderfully accordant with the general Geological results of Zoology, but the real dependence of both the practical and the theoretical Geologist is upon the order of superposition. Thus, when the oolitic system is from any cause obscured, the ranges of chalk above and red sandstone below are immediately appealed to. It is true that in such a case the organic remains might very probably equally decide the doubt; but so long as the relation between the organic remains and the strata is known only in its most general terms, and for a whole series of rocks taken together, while the particular modifications of this relation, which should enable us to apply the theory to different strata in a given region, and to the same or different strata in different regions, are yet matter of investigation, it is evident that no Geologist will consider conclusions depending on organic remains alone as having more than half the force of those which combine also the data of superposition. Their use, in short, so far as relates to this question, *viz.* the relative antiquity of deposits, has ever been *supplementary*, *not principal*. But now we are to take them as our chief guides.

Among the older rocks, such an inquiry, conducted upon the evidence of organic remains alone, would have this advantage, the top of the series to be divided can be clearly defined in the vicinity, though the division may be arbitrary, and so of the base; but in tertiary strata the base can hardly ever be seen, or even safely presumed to be at all known, so many have been the dislocations preceding them, and so abrupt is their junction with the older strata; neither can their uppermost terms be often assigned from a neighbouring type, because the sea, whose bed is the uppermost term, has long since quitted the vicinity of the deposits.

While considering the organic remains of secondary strata, the most successful analogies have always been established by referring to the nearest well known type, whether the object was to compare the fossils of identical or of different strata. Thus the fossils of Normandy present stronger analogies to those of the South of England than to those of Yorkshire; the chalk of England and France produce a greater number of similar fossils than is common to the chalk of England and Sweden, &c. Also the true relation of the oolitic to the lias fossils is best deduced by comparing them in the same district: the oolite of Dundry should be compared with the lias of Bath, rather than with the lias of Yorkshire or of the Western Islands.

Proper mode of employing it for tertiary strata.

These truths are plain, but not unimportant. They lead directly to a particular mode of prosecuting the investigation. For the identification of strata in distant deposits, we must compare them by intermediate terms; for the determining of the relative antiquity of deposits, we must compare, if possible, the marine or fluviatile organic remains which they contain with both the uppermost and lowermost terms of the series, as they occur in the vicinity. Now the uppermost term of this series is certainly no other than the productions of the neighbouring sea and lakes; but the lowermost term is unknown, for the cretaceous system holds no tertiary fossils. We must therefore *assume* the lowest term, and because of the great number of fossils which have been discovered in the calcaire grossier of Paris, this, the lowest really marine deposit of that region, may be chosen as such. If any strata should hereafter be discovered below this stratum and above the chalk, their relative antiquity may be investigated upon the same principles, but the calcaire grossier will in such a case become the upper term, and perhaps the chalk the lower one. Whenever the inquiry can be prosecuted in agreement with these conditions, and the number of organic remains is considerable, the result may be trusted. The organic remains of terrestrial animals can be useful only in comparing terrestrial deposits, lacustrine animals for fresh-water deposits, and marine animals alone must be compared for marine deposits.

As a general upper term of the tertiary series, we are reduced to take the catalogue of existing marine productions, and we are compelled to reason on this, though in fact, through the uplifting of the bed of the sea in some parts, whole races of shells which were then peculiarly situated, (as, for example, a great number of shells in the Mediterranean and in the German Ocean now are,) were probably destroyed within a short period. In such a case the comparison of the fossils is made with a general catalogue indeed, but one from which many of their peculiar analogues have long since been erased, not by gradual change from general physical causes, but by local events.

May we not apply this general argument to the case of the Vienna basin, as compared with the subapennine formations? Is not the former a whole desiccated gulf, and the latter only the dried margin of a gulf? And should we not in this case find the analogy of the fossil and recent tribes strong in Italy, and much fainter in the valley of the Danube, even though the deposits were of exactly the same age?

Again, if we were to abstract from the catalogue of living shells with which we compare the crag of England, the shells of the Northern European Ocean, what would be the effect upon the numerical results of this comparison? Instead of forty species in a hundred now identical with living forms, there would remain two; and the crag would appear as little related to the existing Fauna of the *general ocean* as the London clay, which yet is very much more ancient, and, tried by the test of the neighbouring Fauna, appears to be so.

Lastly, it is to be noticed, that even when both the upper term and the lower term of the series is given from a neighbouring type, the application of the principle of the numerical analogy of species to a variety of basins, for the purpose of ascertaining the relative antiquity of distant deposits, demands the admission that the variation of species, on whatever causes this effect depended, has been proportional always, and in all situations, to the time elapsed. Should this be granted unreservedly, without evidence or examination?

Such are a few of the difficulties in the way of determining, by comparison of organic remains with existing forms, the relative ages of the tertiary strata, and we are not aware that this open statement of them should incur the charge of inconsiderate objection. Long experience has proved to us the inestimable value of the legitimate deductions from the study of organic remains with reference to their antiquity; and it is not to check, but to secure the advances of Geologists in this the only avenue to the classification of tertiary strata, that the unknown conditions of the problem are thus pressed upon their attention.

Mr. Deshayes's investigations.

Were the data upon which the further prosecution of this subject depends not more accurate than these which have been accumulated for the secondary rocks, the determination of the age of tertiary strata in distant basins, with such preliminary difficulties in the general reasoning, must have been indefinitely postponed. But, from various causes, the characters of tertiary shells have been long and carefully studied, and the determination of their species, in consequence of their great number, perfect conservation, and decided general similitude to recent kinds, has been successfully attempted by Lamarck, Brocchi, Sowerby, and other Conchologists. But it is to Deshayes that the Science owes the most lasting obligations of this nature. From the most extended examination of shells both recent and fossil ever attempted, that eminent Conchologist has deduced the most valuable and consistent results which Geology has yet received from any Naturalist, on the subject of the geographical distribution of fossil species, and the numerical ratio of identity between fossil and recent tribes. The Tables which he has constructed from this laborious investigation are given at length in Lyell's *Principles of Geology*, vol. iii.

The order of deductions in these pages being to a certain degree different, we shall not copy those Tables, nor even the results in the way they are given, yet all the statements to be made here are based entirely on the data of Deshayes. For the sake of a common scale, ratios to one hundred will be introduced when useful. Land and fresh-water species are included, but ultimately, no doubt, they will be separated from the Tables of marine shells.

The number of recent species examined by M. Deshayes, for the construction of his Tables, is 4780; of fossil species 3036; together 7816; but 426 of these were both recent and fossil; therefore the whole number of distinct species examined is 7390; and the ratio of the number of species which are both recent and fossil is as 5.7 to 100.

The proportions of univalve and bivalve shells were found thus:

			Ratio to 100.
Living species....	Univalves......	3616	75.6
	Bivalves.......	1164	24.4
		4780	
Tertiary species ..	Univalves......	2098	69.1
	Bivalves.......	938	30.9
		3036	

In these lists land and fresh-water shells are included to the number of 1465 recent, 259 fossil, of which

Fresh-water species .	Living bivalves ..	118	fossil ..	30
	Living univalves.	151	fossil ..	151
Land species.......	Living	1196	fossil ..	78

Tertiary and living species compared.

The fossils are grouped by Deshayes under the following principal localities

1st Division.—Paris, London, Hants. Valognes, Belgium. The fossils of Castel Gomberto and Pauliac are considered the same, nearly, as those of Paris.

2d Division.—Bourdeaux and Dax, Touraine, Turin, Baden, Vienna, Angers, Ronca. The fossils of Moravia, Hungary, Cracovia, Volhynia, Podolia, and Transylvania are considered the same, with very few exceptions, as those of Vienna and Baden.

3d Division.—Italy, Sicily, the Crag. The fossils of Perpignan and the Morea are considered the same, with three or four exceptions, as those of Italy.

				Ratio of living species to 100.
Number of species from the Paris basin	1122	of which	38	are living 3.4
Bourdeaux and Dax.	594		136	22.9
Italy	569		238	41.8
Valognes	332			
Touraine	298		68	22.7
London	239		12	5.0
Sicily	226		216	95.1
Angers	166		25	15.0
Vienna	124		35	28.2
Crag..............	111		45	40.1
Baden.............	99		26	26.2
Turin	97		17	17.5
Belgium...........	49			
Ronca	40		3	7.5

Arranging these approximate results in the order of their ratios we shall have a descending series of analogies from the Sicilian deposits to the Paris basin.

Thus the analogy of fossil species to the living species is,

Sicily	95.0	Allied to existing species in the general ratio of	49 to 100
Italy	41.8		
Crag...............	40.1		
Vienna	28.2	Ditto.	18 to 100
Baden	26.2		
Bourdeaux and Dax	22.9		
Touraine	22.7		
Turin	17.5		
Angers	15.0		
Ronca	7.5		
London	5.0	Ditto....................	3½ to 100
Paris	3.4		
Belgium, Valognes, Castel Gomberto, and Pauliac	none stated.		

In consequence of this comparison, M. Deshayes makes three groups of the tertiary series, according to the ratio of their analogy to existing kinds, as expressed by the brackets above, and Mr. Lyell, from independent researches of a less extended character, was led to form the same scale of analogies, and, moreover, to separate the Sicilian fossils as still more recent than the others. He therefore divides the most recent group into two, and calls them newer and older pleiocene, (or pliocene,) the middle group he calls meiocene, (or miocene,) and the oldest group he calls eocene, as before explained.

Criticism on this scale of analogy would be at present wholly premature, and perhaps not respectful to the eminent Naturalist whose extraordinary knowledge and diligence have presented us with these most beautiful and impressive results. It appears to deserve remark, however, that the inland situations of the Vienna and Baden tertiaries may unfavourably influence the comparison for the fossils in these localities, from the causes before stated; and, perhaps, it may appear, if that circumstance could be properly compensated, that these localities should be removed from their association with Bourdeaux; and joined to the subapennine deposits, according to what seems to have been the inference of the observers on the spot.

Relation of tertiary shells to those in the Pans;

The subject may be contemplated in another point of view; instead of inferring the relation of the fossil shells to one common upper term, *viz.* the shells of the actual seas, they may be compared to what has been assumed as the lowest term of the series, the basin of Paris. Because of the very great and admitted resemblance of the shells of Paris, London, Valognes, and Belgium, these may be grouped together, and we shall have the lowest tertiary epoch yet clearly made out represented by 1238 species, of which 42 are recent, and 46 are found in the deposits above them.

			Ratio to 100.
Shells of Bourdeaux and Dax …	594, of which	27 are also Parisian,	4.6 nearly.
Touraine	298	8	2.6
Angers	166	7	4.2
Vienna	124	3	2.4
Baden	99	2	2 0
Turin	97	7	7.0
Ronca	40	10	25.0
Sicily. Italy, the Crag…	777	4	0.6

From this Table we have the following scale for comparison with that previously given, the analogies to the Parisian formation increasing downwards.

Sicily, Italy, the Crag ……….analogy	0.6
Baden	2.0
Vienna	2.1
Touraine	2.6
Angers	4.2
Bourdeaux and Dax	4.6
Turin	7.0
Ronca	25.0

The accordance of the two scales is very remarkable, and by both of them Ronca, as Deshayes conjectured, appears to demand a place in the Parisian group. Vienna, Baden, and Touraine here appear less related to the Parisian group.

to those of Touraine and Dax.

The relation of the Touraine fossils and the Bourdeaux and Dax fossils to the subapennine formations appears to be almost exactly the same; their relation to living types is also almost exactly the same. It is therefore evident that these beds may be joined together to make a new common term. We shall then have 743 species, and the analogy to this common term is for

Vienna	85.5
Baden	49.5
Turin	47.4
Angers	30.7
Subapennine	22.7
Parisian epoch	4.0

The analogy of the

Vienna and subapennine fossils is..	40
Turin and subapennine	29
Bourdeaux and subapennine	22.5
Touraine and subapennine	23.4

General results.

The general result of these numerical comparisons would seem to give the following scale of antiquity amongst the several deposits.

Lyell's Name.

Sicilian deposits. } Newer pleiocene. } Pleiocene.
Crag —— Subapennine deposits. } Older pleiocene. }
Vienna beds.
Touraine——Bourdeaux and Dax——Baden——Turin. } Meiocene.
Angers.
The Parisian and London deposits. Eocene.

Having thus shown from M. Deshayes's data, the origin of the groups which he uses, and of the names of Mr. Lyell, we may present the following general results of the investigation of those authors, and refer to themselves for abundance of further information.

Eocene, or Parisian period. This should perhaps be considered as strictly applicable to the lower marine formation of the Paris basin, because it is almost wholly on the shells of that formation that the classification is founded.

Number of species of shells of this period	1238
Number of species also found in the meiocene period..	66
Number of species also found in the meiocene and in the pleiocene period, and which may therefore be considered as characteristic of the whole tertiary system	17
Number of species identical with living kinds	42

Meiocene Period.

Number of species of shells	1155
Number of species common to the meiocene and the two other epochs	134
Real number of species of this period	1021
Number of species also found in the pleiocene period..	196
Number of species identical with living kinds	176

Pleiocene Period.

Number of species of shells	777
Number of species identical with living kinds	350
Whole number of species of shells of the tertiary system	3036

Names of the seventeen shells which are characteristic of the tertiary system.

Four extinct or unknown in a recent state	Dentalium coarctatum. Tornatella inflata. Bulimus terebellatus. Corbula complanata.
Thirteen still living	Dentalium entale. strangulatum. Fissurella græca. Bulla lignaria. Rissoa cochlearia. Murex fistulosus. tubifer. Polymorphina gibba. Triloculina oblonga. Lucina divaricata. gibbosula. Isocardia cor. Nucula margaritacea.

Organic Remains of the Tertiary Strata.

The statement previously made that M. Deshayes has himself examined 3036 species of tertiary fossils, must be a sufficient reason for not following in respect of these strata the plan adopted for the less numerous organic remains of the secondary and primary rocks. There is indeed not the same inducement or utility in such extended lists of tertiary fossils. They would not add any thing to the knowledge of periods given by the investigation which we have just ended, and the general resemblance in tertiary fossils of all ages and localities is too great to confer any particular interest on the enumeration of species. There is, probably, no more remarkable statement in any Science, than that of all the 3036 species of tertiary shells, *not one* should be found in any of the older strata. This statement could only be made and can only be verified by a skilful Conchologist; but the eye least practised in such observations can recognise the same proposition in another form. Many of the tertiary genera of fossil shells, and especially those which predominate in these strata, are either utterly unknown or very seldom seen in secondary strata, and thus whole tribes of shells are instantaneously pointed out, by one who is no Conchologist, as tertiary fossils.

The most useful lists of tertiary fossils will be such as are capable of direct comparison on leading points with catalogues formerly given for the secondary rocks. For this, the generic name and number of species must in general suffice. The marine deposits should be separated from those of fresh-water. The numbers of the species of shells are taken from Deshayes's Tables. The remainder from Brongniart, *Tableau des Terrains.*

Lacustrine Tertiaries.

Their age to be inferred from the remains of aquatic races.

As the marine shells afford the best or rather the only grounds for plausible deductions concerning the relative ages of the tertiary strata deposited from the sea, so the fresh-water shells and land shells must be employed to indicate the relative age of the many lacustrine deposits which diversify the tertiary districts, and cannot always, by any rule of superposition, be referred to either of the lacustrine deposits of Paris. In this research the plants also yield highly valuable evidence, but the land mammalia found with them ought surely to be excluded from the data which are to determine the age of the lacustrine sediments; because the changes of their races may, for ought we know at present, have been governed by wholly different conditions from those which affected the fresh-water or land shells and plants. Indeed, the case of shelly and osseous marl at Market Weighton, as well as every peat bog containing the Irish elk, proves that this suggestion is well founded. The era of the quadrupeds is to be determined from that of the lakes, not assumed to help out the deficient evidence concerning these latter.

A few cases, selected from the great number of tertiary lacustrine deposits, for the sake of some peculiar facts which they display, may now be introduced, to illustrate the condition of the surface of the land during the tertiary epoch. In general it is to be observed that, just as at the present day lakes sometimes occur on certain streams, in several parts of the valley, at different heights above the sea, and spread their waters over the Jura limestone, chalk, tertiaries, or primary strata, according to the nature of the country, so it was in the older time; and no criterion of the age of a fresh-water deposit is to be drawn from the marine nature of the strata on which it rests beyond the mere inference that it was posterior to such strata. If, as must frequently happen, the circumstances of these different lakes are unlike, the deposits in them may be related neither by similarity of order, nor identity of composition, but it is probable that some analogy will be traceable in their organic remains.

In the basin of Paris, gypsum occurs only in the lower fresh-water deposit, yet the gypsiferous fresh-water deposit of Auvergne, is supposed by Brongniart to be of the age of the upper fresh-water deposits.

Central France.

The fresh-water district of central France occupies considerable tracts along the lines of the Loire and the Allier, and is extended Northwards on the latter river, so as to approach towards the proper basin of Paris. The interesting phenomena presented by these deposits, where they have been subjected to volcanic agency about Clermont, the Cantal, and Puy in Velay, will be mentioned hereafter. Along the Allier, granite is the general basis of the fresh-water strata, which consist of sandstone and conglomerate, containing pebbles of all the primary rocks of the vicinity, but not of the volcanic rocks. Above these are green and white very finely foliated marls, full of the small bivalve crustaceous shells of cypris; thin tufaceous limestones, sometimes full of the larva—cases of phryganidæ; and the highest group of all in a few places is composed of gypseous marls. The most singular fact mentioned by Messrs. Lyell and Murchison, in their description of this country, is the remarkable condition of two of these groups. The lowest conglomerate series puts on almost exactly the appearance of the English old red sandstone, with its purple and green spotted marls, and even its nodular limestone or cornstone; and the limestone in the upper part of the series actually becomes oolitic at Vichy and Gannat, and yields a building stone like that of Bath, and of equal beauty; soft in the quarry, but gathering hardness by exposure. With what astonishment would the Geologist, acquainted with the fossils of the English oolite, gather in this oolite of Gannat, land shells and bones of quadrupeds, like those of the gypsum of Montmartre!

The lacustrine formation of the Cantal, rests in the same manner upon primary rocks, with sandy and gravelly beds below, gypsiferous marls, beds of flint and limestone above. This fresh-water limestone, and its accompanying flints, are described by Mr. Lyell as possessing a strong resemblance in mode of arrangement to the marine chalk and flint; the flint of the fresh water, black within, white without, and undergoing the same changes of superficial colour on exposure as the chalk flints of England.

Provence.

The same Geologists have been very successful in tracing the fresh-water deposits of Aix in Provence, which have yielded a large number of fossil insects, some fishes, and land plants of existing genera. M. De Serres also has described this locality, and studied the insects with attention. The general basis of the Aix tertiaries, is a rock of the oolitic system, inclined and contorted in position, with gryphæa, belemnites, and ammonites. The lacustrine deposits are in the lower part a series of carboniferous limestones and shale, with stony bituminous coal in several seams which altogether amount to five feet in thickness. The limestone is compact, grey, blue, and black, and resembles the mountain limestone of England. Fresh-water shells (cyclades, melania, planorbis, unio) accompany these beds, and gyrogonites are found in the coal itself. Micaceous sandstones and shales, with earthy limestone and limneæ, come on above; and these are succeeded by red marl and fibrous gypsum, also characterised by the presence of limneæ and planorbes. Under and above the town of Aix, the upper series of the basin is observed to consist of red sandstone and conglomerate, covered by white and pink-coloured marlstone and marl; and above all is a triple succession of gypsum and marls, overlaid by white calcareous marls and marlstone, with calcareo-silicious millstone and resinous flint, containing land and lake shells. It is in these beds that the fossil fish occur abundantly, and leaves and branches of flabellaria, laurus, buxus, &c. are found. The insects are obtained from a parting in the upper gypseous beds. They are, with one exception, all land insects; and from the united testimony of M. De Serres and Mr. Curtis, referable or nearly related to existing genera, principally of the orders diptera and hemiptera, some coleoptera and hymenoptera, but only one lepidopterous insect: sixty-two genera are particularly enumerated by M. De Serres. May we not compare this curious and as yet almost unique fact in tertiary Geology to the collection of insects, leaves, and branches, which, when swept down by Spring or Summer floods, affords a rich harvest to the Entomologist on the borders of the rivers in the North of England?

Œningen.

The limestone quarries of Œningen, near Schaffhausen, have long been celebrated for abundance of mammalia, birds, reptiles, fishes, insects, and plants, identical or very similar to existing kinds. The section of the whole deposit is given by Mr. Murchison, who brought from this locality, in 1828, one of the most remarkable fossils which has ever been found—the entire and connected skeleton of a fox. The upper quarries offer a section of thirty feet, the beds changing downwards from brown clay into cream-coloured indurated marl, and afterward into a fissile fetid marlstone, containing flattened shells of planorbis, small limneæ, and cyprides; to these succeeds light-coloured, fetid, calcareous building stone, beneath which is a finely laminated bed, containing insects, cypris, shells of anodon, and many plants; then follow two thin beds of fetid limestone, in the upper of which a large tortoise was found, and in the lower one the fox. Below are slaty marls and marlstones, limestone, and building stone, with a repetition of finely laminated layers of marl, with plants and fishes; the general base is the molasse of Swisserland. Excepting this fox, which is very much allied to the common fox of Europe, all the other quadrupeds found here are rodentia. The insects and plants belong to European genera.

These descriptions of some of the most interesting lacustrine deposits, will render it unnecessary to particularize other numerous cases in Swisserland, Germany, Hungary, Italy, and Spain, which present nearly the same phenomena, and appear to occupy the whole interval of time from the lower fresh-water formation of Paris to the diluvial era, and to be represented by an equally continuous series of detached desiccated lakes from that era to the present time.

Lignite

There is, however, another kind of fresh-water deposit which requires a short notice. Lignite, or wood coal, has long been known in France, in connection with the plastic clay group and other more recent strata, and also in the Isle of Wight. The same kind of carbonaceous deposit is of value in the molasse of Swisserland, and very extensively spread over the North of Germany, and in the Valley of the Rhine; it also interlaminates extensively the marine tertiaries of the basin of Vienna and the border of the Carpathians: lignitic coal has therefore been considered as even peculiar to the tertiary era. This is not quite correct, yet the generalization is of more importance than perhaps we may at present perceive.

The whole mass of these lignites is made up of land plants, mostly or wholly of dicotyledonous tribes, and they are accompanied by marls, land and fresh-water shells, and, in places, by the bones of paleotheria, anthracotheria, beaver, &c. The fixing of their relative age is hardly possible by evidence drawn from themselves alone, for the shells and plants are few, and the quadrupedal remains very local. If we attempt to fix their date by that of the marine strata which they divide, the uncertainty of the latter datum must, in a great measure at present, frustrate the attempt. Perhaps the most recent deposit of this kind mentioned on the Continent, is that described by De Beaumont as associated with the older diluvium, as it has been considered, which that author ascribes to the uplifting of the Western Alps. This deposit bears marks of slow and tranquil accumulation in a lake, contains planorbes in the layers of clay which alternate with it, and sometimes shows as many as four beds; it rests on and is covered by pebbles, which indicate violent watery action.

It is highly probable that lignite has been formed at many periods, and that deposits of this kind will be found at intervals from the plastic clay, through the diluvial gravel and clays to the modern alluvial peat bogs, which they so much resemble in alternation and repetition of materials, paucity of shells, occasional occurrence of quadrupedal remains, and almost every obvious circumstance.

Lignite of Bovey Tracey.

Bovey Tracey, in Devonshire, is the only locality in England where tertiary lignites are worth working; the exact Geological age of this deposit is not known at present. Pipe-clay of some value lies with it. Dr. Milier, in the *Phil. Trans.* vol. li. describes this deposit in a very interesting manner. The whole series dips to the South about twenty inches in a fathom. The perpendicular thickness of these strata, including the beds of clay with which they are intermixed, is about seventy feet. There are about six of each, and they are found to continue Eastward, in an uninterrupted course, to the village of Little Bovey, a mile distant, and probably much further. The strata of coal, near the surface, are from eighteen inches to four feet thick, and are separated by beds of brownish clay, nearly of the same dimensions, but diminishing in thickness downwards, in proportion as the strata of coal grow larger; and both are observed to be of a more compact and solid substance in the lower beds. The lowermost stratum of coal is sixteen feet thick; it lies on a bed of clay, under which is a sharp green sand of seventeen feet thick, and under that a bed of hard coarse clay, into which they have bored but found no coal. From the sand arises a spring of clear blue water, which the miners call mundic water, and a water of the same kind, trickling through the crevices of the coal, tinges the outside of it with a blue cast. (Phosphate of iron.)

Amongst the clay, but adhering to the coal, are found lumps of a bright yellow loam, which burn with an agreeable scent. (Retinasphalt.) Some of the coal is black, and nearly as heavy as pit coal; this is called stone coal; but the most remarkable sort resembles wood in the grain and appearance so much as to be called wood or board coal. Some plants like grass and reeds lie in the alternating clays, which are in part carbonaceous.

The following section of the Meissner by M. Herndeshagen (*Leonhard Taschenbuch*, 1817) gives the most usual relations of the brown coal and basalt of that celebrated locality.

1. Dammerde.
2. Greenstone and basalt, 50 to 80 fathoms ..... 300 to 480 feet.
3. Schwül, (blind coal,) a bituminous laminated clay, hardly to be distinguished from true coal .... ½ to 5 feet.
4. Kohlenflöz, in all 3 to 14 fathoms thick, *viz.*
   - *a.* Stangenkohle (prismatized).. 1 to 4 ft....
   - *b.* Glanzkohle (sp. gr. 1 438) .. 3 to 18 ft ..
   - *c.* Pechkohle (sp. gr. 1.346) ... 3 in. to 3½ft.
   - *d.* Brownish black (sp. gr. 1.259) 3 to 4 ft. ... } 3 to 14 fath.
   - *e.* Light brown light coal (sp. gr. 1.230) .... 4 to 8 fath..
   - *f.* Fossil wood, called stockwerk 6 in. to 4 ft.
5. Liegende, (sill or sole of the coal,) sp. gr. 2.545
6. Triebsand .... ½ fathom.
7. Blue marl, on the East of the mountain, with gypsum .... 10 to 15 fath.
8. More or less friable sandstone 1 fathom, then sandstone to the foot of the mountain on the East side, but on the West side muschelkalk.

Organic Remains of Lacustrine Tertiaries.

tuberculosa	Isle of Wight.
medicaginula.........	Montmorency, Sanois, Trappes near Paris.
helicteres	Pleurs, Department de l'Aisne.
Phanerog. gymnosperma.	
Pinus pseudostrobus	Armissan.
Taxites Tournalii	Ditto.
Phanerog. monocotyledonea.	
Smilacites hastata	Ditto.
Flabellaria Lamanonis.....	Aix en Provence.
Endogenites	Montmartre.
Poacites	Aix.
Phanerog. dicotyledonea.	
Comptonia dryandræfolia...	Armissan
Betula dryadum	Ditto.
Carpinus macroptera.	Ditto.
Phyllites lævigata.........	Aix, Armissan, Pavia, &c.
Geslini...............	Aix.
Nymphæa arethusa	Longjumeau.
? Culmites anomalus	Ditto.
Carpolithes thalictroides....	Ditto, Isle of Wight.
ovulum..............	Longjumeau.
Exogenites	Palaiseau.

CONCHIFERA.

Unio Solandri, Sow.	Isle of Wight, Hordwell.
Cyclas	Aix en Provence.
Anodonta Lavateri........	Œningen.
Mya ? gregaria, Sow.	Headon Hill.
Corbula nitida, Sow.	Isle of Wight.
Cyrena pulchra ?	Hampstead Bay; Skye.
Mytilus Brardii, Sow.	Hordwell.

MOLLUSCA.

Gasteropoda.

Planorbis rotundatus, Sow. ...	Paris, Salinelle, (Gard,) Quercey.
cornu	Paris.
euomphalus, Sow.	Isle of Wight.
prevostinus...........	Ditto, Paris.
Planorbis prominens.........	Salinelle.
compressus	Ditto.
lens	Isle of Wight, Paris.
cylindricus, Sow.	Isle of Wight.
Limnea fusiformis, Sow.	Headon Hill.
minima, Sow.	Ditto.
maxima, Sow.	Binstead.
longiscata, Lam.	Headon.
pyramidalis, Sow......	Ditto.
columellaris, Sow.	Hordwell.
cornea	Paris, Colle en Siennois.
fabulum	Paris.
ventricosa	Ditto, Bruere. (Cher.)
inflata	Bruere.
cylindrus	Ditto.
strigosa	Le Locle near Neufchatel.
elongata.............	Paris.
acuminata	Ditto.
æqualis..............	Salinelle.
pygmæa.............	Ditto.
ovum	Paris.
Paludina affinis.............	Saliuelle.
impura..............	Quercy.
Hammeri............	Isle of Wight, Bouxweiler.
carinata	Paris.
Ancylus elegans.	Hordwell.
deperditus	Salinelle.
Melania fasciata	Isle of Wight.
Melanopsis carinata	Newport, Isle of Wight.
brevis	Hordwell, &c.
Phasianella orbicularis	Shalcomb, Isle of Wight.
angulosa	Ditto.
minuta	Ditto.
Potamidum Lamarckii	Paris, Aurillac, Nonette, nea Issoere.
acutum..............	Isle of Wight.
ventricosum..........	Ditto.
Indusia tubulata ?...........	Moulins, Auvergne, Colle.
Cyclostoma truncatum	Paris, Carnetin.
elegans antiquum . . .	Paris.
mumia	Ditto.
Helix globosa	Shalcombe, Isle of Wight.
Lemani	Paris.
Desmarestina	Ditto.
*Ramondii............	Orleans, Auvergne.
Cocqui	Ditto, ditto.
Bulimus pygmæus	Paris.
terebra	Ditto.
atomus	Paris, Le Puy.
pusillus	Ditto.
Pupa Defrancii	Paris and Auvergne, in a piperine.
muscorum	

ARACHNIDA, INSECTA, &c.

Aranea	Aix en Provence.
Phrynus.	
Coleopt. Dytiscus.	
Staphylinus.	
Buprestis.	
Melolontha.	
Curculionidæ	10
Trogosita.	
Hylophagidæ......	5
Orthoptera	8
Hemiptera	20
Neuroptera Libellulidæ.	
Hymenoptera	8
Lepidoptera	2
Diptera	15

FISHES.

Mugil cephalus.............	Aix in Provence.
Perca minuta	Ditto and Paris.
Cyprinus squamosus.........	Ditto, ditto.
bipunctatus..........	Œningen.
jises	Ditto.
capito...............	Ditto.
minutus	Paris.
ictus	Rochesaure. (Ardeche.)
tinca	Cadix.

Pæcilia Lametherii	Paris.
Anormurus macrolepidotus	Ditto.
Esox	Œningen.
Amia ignota	Ditto.

REPTILES.

Crocodilus gypsorum, Cuv.	Paris, analogous to alligator.
Argentoni, Cuv.	Argenton, ditto.
Salamandra gigantea	Œningen.
Triton palustris	Ditto.
Rana	Ditto.
Trionyx gypsorum, Cuv.	Paris.
Maunoir	Aix and Paris.
des molasses	La Grave, L'Agenois, Le Quercy, Haute Vigne, (in Lot and Garonne,) Castelnaud.
Emys gypsorum, Cuv.	Paris.
Testudo of Aix	Aix.

BIRDS.

Several species	Paris, Auvergne, Œningen.

MAMMALIA.

Palæotherium magnum	Paris, La Grave, Dordogne, (also Binstead, Isle of Wight.)
medium	Ditto.
crassum	Ditto.
latum	Ditto.
minus	La Grave, Paris.
minimum	Paris.
aurelianense	Orleans.
Isselanum	Issal near St. Papoul.
Anoplotherium commune	Paris, (also Binstead, Isle of Wight.)
secundarium	Paris.
Xiphodon gracile	Ditto.
Dichobunes leporinus	Ditto.
murinus	Ditto.
obliquus	Ditto.
Chæropotamus Parisiensis	Ditto.
Anthracother velaunum	Puy en Velay.
Lophiodon major	Argenton, Issel, Soisson, Gannat, Montabuzard.
secundarius	Argenton.
minor	Paris.
pygmeus	Ditto.
maximus	Bastberg, near Bouxweilor.
secundus	Bastberg.
Monspeliensis	Boutonnet, Montpelier.
quintus	Argenton.
Canis Parisiensis	Paris.
Vulpes	Œningen.
Genette des Platrieres	Paris.
Coati des Plat	Ditto.
Didelph. Parisiensis	Ditto.
Ecureuil des Plat	Ditto.
Loir des Plat	Ditto.
—— second	Ditto.

Lignitic Tertiaries.

PLANTS. (No marine.)

Coniferæ.	
Pinus sphærocarpa	Erxleben near Helmstædt.
ornata	Walch in Bohemia.
familiaris	Triblitz in Bohemia.
Taxites acicularis	The Meissner.
tenuifolia	Comothau in Bohemia.
diversifolia	Cassel.
Langsdorfii	Nidda near Frankfort.
Juniperites brevifolia	Comothau.
acutifolia	Ditto.
? aliena	Schmetzna in Bohemia.
Thuya gracilis	Comothau.
Langsdorfii	Nidda.
graminea	Perutz. (Bohemia.)
Naiadæ.	
Potamophyllites multinervis	Mont Rouge near Paris.
Palmæ.	
Palmacites echinatus	Wailly near Soissons.
Flabellaria raphifolia	Hæring in Tyrol, Lausanne, Vinacourt near Amiens.
Phænicites pumila	La Chartreuse de Brive. (Velay.)
Cocos (Parkinsonis)	(Sheppey.)
Faujasii	Liblar near Cologne.
Burtini	Woleuve near Brussels.
Monocotyled. incerta.	
Endogenites	Liblar, Horgen near Zurich.
(Amomocarpum depressum)	(Sheppey.)
(Pandanocarpum pyramidat.)	(Ditto.)
Dicotyledonea.	
Amentaceæ.	
Comptonia acutifolia	Comothau. (Bohemia.)
Salix ?	Nidda.
Populus ?	Ditto.
Castanea ?	Menat.
Ulmus	Comothau.
Juglandeæ.	
Juglans ventricosa	Nidda.
lævigata	Ditto.
Acerineæ.	
Acer Langsdorfii	Ditto.
Dicotyl. incerta.	
Exogenites	Universal.
Phyllites cinnamomifolia	Meissner.
Carpolithes (many)	Nidda.
Leaves, &c. (many)	Ditto.

CONCHIFERA.

Unio ovatus, St.	Swisserland.
Cyclas palustris	Ditto.
Cyrena antiqua	St. Marguerite. (Dieppe.)
tellinoides	Soissons.
cuneiformis	Ditto.
Crawfordi	Irawadi.
Ostrea Bellovacina.	
incerta.	

MOLLUSCA.

Nerita globulus	Epernay.
pisiformis	Ditto.
sobrina	Ditto, Soissonnois, &c.
Ampullaria Faujasii	St. Paulet. (Gard.)
Melanopsis buccinoides	Epernay, Soissons, Cuiseau, Headon Hill, Italy, Sistos, &c.
costata	Soissons.
Melania triticea	Epernay.
Escheri	Kœpfnach near Zurich.
Paludina virgula	Epernay.
unicolor	Soissons.
Desmarestii	Paris.
Limnea longiscata	Ditto.
Physa antiqua	Epernay.
Planorbis rotundatus	Soissonnois, Bagneux, Paris, &c.
regularis	Cezenon. (Herault.)
incertus	Bagneux, Epernay.
punctatus	Ditto, ditto.
Prevostinus	Paris.
Cerithium melanioideum funatum Ampullaria depressa	Epernay, Anvert, Bagneux, Paris, &c.

REPTILIA.

Crocodilus d'Auteuil	Near Paris.
vulgaris	Irawadi.
de Provence	Mine de Memet(Provence.
Leptorhyncus	Irawadi.
de l'Inde	Ditto.
Trionyx de l'Inde	Ditto.
Salamandra ogygia, Goldf.	
Triton Noachicus, Goldf.	
Rana diluviana, Gold.	
Ophis dubius, Goldf.	

MAMMALIA

Mastodon angustidens	Kœpfnach near Zurich.
elephantoides	Irawadi.

Mastodon latidens	Irawadi.
Hippopotamus	Ditto.
Rhinoceros	Kœpfnach, Irawadi.
Tapir	Irawadi.
Anthracotherium magnum	Cadibona. (Tuscany.)
minus	Ditto.
minimum	Ditto.
alsaticum	Lobsan.
silistrense	Caribari. (Bengal.)
Lophiodon Laonnense	Department de l'Aisne.
Bos	Irawadi.
Castor des lignites	Kœpfnach.

Dislocations of the Tertiary Strata.

After the deposit of the chalk and the plastic clay strata, and after the accumulation upon it of several regular marine tertiary strata, extensive disturbances happened, by which the chalk and all the older strata were thrown into new positions, and the whole configuration of the land in the Northern zones was greatly changed.

South of England.

In England, the effects of general convulsions at this epoch are very striking in the Southern Counties, and chiefly referable to two nearly parallel great undulations of the strata, of a peculiar character, ranging East and West. These undulations are of such a kind, that there are two axes of elevation and two parallel troughs. The Northern trough is nearly in the line of the Thames from London to Reading, beyond which it appears to end; the Southern trough is directed along the Solent, towards the extension of the chalk beyond Dorchester, beyond which it also appears to end. The Northern axis of elevation passes through the Weald of Kent and Sussex, South of Guilford to Highclere in Hampshire, and is continued along the Vale of Pewsey, but ends toward Devizes. The Southern ridge of strata passes through the Isles of Wight and Purbeck, and between Weymouth and Bridport, and ends at some point in the Channel before arriving at Torbay.

These great undulations appear evidently caused by violent elevation of the strata along the two lines described; and it is exceedingly remarkable that the effect of the convulsion is such, that in each case the declination of the strata on the North side is generally very steep or *even vertical*, as at Guilford on the one ridge, and in the Isles of Wight and Purbeck on the other, while on the South side the chalk in Hampshire, and the green sand and oolitic groups in the Isles of Wight and Purbeck, are nearly level or slope gently to the South.

It is further observable, that for a certain length in the middle of each axis of elevation the strata are vertical or nearly so, on the North side, but on each side of this length the inclination becomes less and less violent, and at considerable distances, in one of the ridges, is reduced to a gentle slope. Thus, on the Northern ridge, the strata are violently inclined along the line by Highclere in Hampshire, (*where the chalk attains its greatest elevation in England,*) and at Guilford, but both Westward toward Devizes, and Eastward toward Kent, the slopes become gentle. Also on the Southern ridge, the strata are *highly* inclined North of Weymouth, *nearly* vertical in the Isle of Purbeck, but *absolutely* vertical at the Western end of the Isle of Wight, and in Culver cliffs (Eastern end of the Isle of Wight) instead of being vertical are inclined 70° North.

From these data we may infer confidently that the disturbing force acted from below along particular lines, and most violently at certain points in these lines; and because of the unequal declinations of the strata on the opposite sides of the ridges, we may perhaps admit the force to have been exerted in *an oblique direction*. This latter conclusion has often been suggested to us while considering the ordinary phenomena of *faults*.

Diluvial Deposits.

We have now concluded the history of the deposits formed on the beds of the ancient sea, in its depths, along its shores and in its estuaries, and we have noticed the contemporaneous or alternating accumulations from the fresh waters which then flowed upon the Earth. The tertiary system of strata, by showing us remarkable alternations of fresh-water and marine deposits, appears to establish a connection between the ancient and the modern World, between the subaqueous and the elevated land.

The whole of that system presents us with strong analogies to the present order of things, in its races of animals and plants; and its fresh-water deposits have often a clear relation to the present level of the continents, and on this account might be viewed as the oldest of the alluvial formations.

Yet upon closer inquiry it will be found that in many cases a very strong line of distinction is drawn between the tertiary formations and the true alluvial accumulations, by the intervention of an irregular mass of deposits, evidently produced by inundations of extraordinary violence upon the face of the dried and inhabited Earth. These deposits are so extensive, and over large tracts of the Earth's surface have so much of a common character, that they have very generally been classed as the productions of one turbulent period in the process of the formation of the Globe, and termed the Diluvial deposits.

Origin and use of the term.

This term was first employed by Mr. Smith, and when subsequently adopted by the English School of Geology, it was often understood to refer to the effects of the Noachian Deluge; and though on this point opinions are now more unsettled and various, the term may still be very properly employed by Geologists of every School to mark the effects of turbulent inundations upon the inhabited land, happening within a particular period in the History of the Globe. In this sense we employ it.

Without entering upon the unprofitable history of the delusions in which Geologists have involved themselves on the subject of the Noachian Deluge, it will be proper to remark that all discussions of this nature are useful or injurious according as they are carried on independently of or in connection with Theology. Burnet and Woodward, by mixing up false hypotheses with Scriptural History, retarded the progress of Geological Science, and sanctioned a perverse application of the Mosaic narrative to support every new, fanciful, and unsubstantial theory.

We must always bear in mind that it does not follow that all deluges must be referred to the Noachian flood; certainly many turbulent waves have traversed the Globe before the creation of man; some local deluges have happened since the days of Noah. It may therefore very possibly be true that the turbulent waters of which we are now to trace the effects upon the surface of the Earth, may be quite independent of the Deluge of Scripture; we have no right to *assume* any connection between them; and at all events it will be prudent before thus entangling ourselves in fetters which it may be difficult to unclasp, to wait for a full investigation of the subject. Many curious questions of time and circumstance are involved in such a comparison which it will be wise to reconsider.

There is nothing in Geology less improbable than the occurrence of a period of violent watery action, for in the course of our survey of the stratified rocks, we perceived clearly that, during their production, long periods of regular and ordinary action have been frequently succeeded by temporary disturbance. The epochs of these disturbances relatively to other phenomena are precisely assignable. They differ in importance, and while some are so great and extensive as to afford means of classifying the strata over large surfaces of the Globe, others seem to have happened locally and irregularly.

The present system of Nature may be considered as one of the periods of regular action, and the effects now produced upon the land and in the sea are of the same kind as those occasioned during the comparatively tranquil periods of older nature, because upon the whole the levels of sea and land are constant. But the deposits called diluvial are characteristic of a period of watery tumult and disturbance of the most extensive kind, and are to be associated mentally with other great epochs of disturbance which mark temporary convulsions in the ancient system of Nature. This watery tumult differs, however, from all anterior deluges, by the circumstance that we are looking upon the land and reading there the traces left by violent waves, while those of ancient times are known to us only by the effects they produced in the sea.

Proofs.

We shall now present the proofs of such a system of turbulent waters having passed over large portions of the surface of the inhabited Earth, since the formation of all or nearly all of the stratified rocks now visible above the Ocean, and since the present continents were dried, elevated, and inhabited.

Detritus from the Cumbrian mountains.

1. Without venturing to assert that every region of the Earth's surface is covered by the water-moved ruins of rocks, and waste of distant mountains, in situations to which existing streams could not carry them, we may state that observations of this nature are general for all parts of the Continent of Europe, Northern Asia, and Northern America, Countries which have been, better than any other, explored by Geologists. In all these regions, great deposits of gravel, sand, and clay, containing in more or less abundance portions of all the known rocks and strata, lie spread over formations of every age, primary, secondary, and tertiary. There is no order in the arrangement of these heterogeneous materials, no constant series or succession of deposits, but the utmost confusion and irregularity. The materials lie sometimes in valleys, often on hills, crossing in their course both hills and valleys, and appearing to have little relation to the track of the existing streams, though sometimes evidently influenced by the great physical features of the districts. Though the subject of the direction of diluvial currents, with reference to local geography, has not been sufficiently attended to, even in England, we are able to bring forward some striking instances in support of the preceding statements. It is well known that the mountain group of Cumbria encloses remarkable kinds of granite, sienite, and other rocks, and that they are separated from the Eastern parts of the Island by a long unbroken range of carboniferous limestone stretching from the Tyne to the Aire. A considerable hollow every where divides these ranges; and in some parts, as in the vale of Eden, the hollow is from 1000 to 2000 feet, or more, below the summits on either hand. The lowest point in the whole line of carboniferous limestone, which offers itself directly to the West, is on Stainmoor, about 1500 feet above the sea. Now by the force of the currents of water alluded to, blocks of the curious porphyritic granite of Shap Fells have been removed from their original sites, (1500 feet above the sea,) swept over a ridge of limestone rocks about Orton, into the red sandstone vale of Eden, and from this deep and ancient vale lifted up the steeps of Stainmoor to the very summits of the pass. From thence they have been urged forward as from a new centre, and spread in a radiating manner over the South of Durham, and the whole extent of the vales of York and Cleveland, to the foot of the Hambleton Hills and the Wolds. Against these great barriers, considerable quantities of the rocks of Cumberland, and likewise of the carboniferous system of Yorkshire, are collected, but a large portion of the débris has also travelled over and beyond parts of these high districts and reached the sea side, where many of the cliffs are covered by blocks swept from Cumberland and North-Western Yorkshire. In passing from Shap Fells to Holderness, the granitic boulders have been transported across two deep vales, and over two elevated ranges of hills. In passing over these hills, we clearly perceive that the blocks were wafted by the easiest ascents. This is remarkably the case at Stainmoor, the lowest point in the long carboniferous summit, and the only one crossed by the diluvial boulders. It is therefore evident that at the period when these violent waters flowed over the North of England, the land had assumed its present general shape and altitude; it is also clear that the floods were influenced in their direction by the great physical features of the country, but that at particular points they were of force and volume enough to overcome these natural obstacles.

Besides the porphyritic granite of Shap other remarkable rocks of the Eastern part of the Cumbrian mountains have followed the same course. The hypersthenic and sienitic rocks of Carrock Fell, the brecciated and amygdaloidal slates of Grasmere, Ulswater, &c. may be often recognised in the same situations. Perhaps the most instructive of all examples derived from this country is that furnished by the red "brockram" of Kirby Stephen. This member of the saliferous formation is easily known by its fragments of carboniferous limestone imbedded in red sandstone, and its native site is in the depth of the vale of the Eden. From this deep repository it has been lifted by the diluvial currents over Stainmoor, and thence carried with the granites and other rocks of the Cumbrian group.

The currents to which these effects are ascribed, must have flowed from the North-West. From the Western part of the Cumbrian group of mountains, currents flowing nearly from North to South have carried the granite of Ravenglass and Muncaster along the low ground West of the carboniferous chain of Yorkshire and Lancashire to the vicinity of Manchester, and through a great part of Staffordshire; but this sort of granite has no where crossed the carboniferous chain, to spread down the valleys of the Aire, Dun, Derwent, or Dove. In this case, as in the former, it is evident that the current was directed by the great physical features of the country, which were the same then as now.

From the Lickey Hill.

The quartz pebbles of the Lickey have been widely diffused over the plains of Warwickshire and Gloucestershire to the foot of the Cotswold Hills, but on arriving at this barrier they are stopped, except at two low points, the summits of the valleys of the Cherwell and the Evenload. Down these valleys, and along their borders, the pebbles hold separate courses till the streams unite near Oxford, after which the general course of the valley of the Thames is the line of the diluvial deposits.

A tendency to be arranged in narrow, longitudinal spaces is sometimes observable in the diluvial accumulations. In Lincolnshire a long narrow ridge of diluvial chalk runs out in a South-Westward direction by Faldingworth. In Yorkshire the lias boulders from Robinhood's Bay keep nearly parallel to the present North and South line of coast; and the flinty gravel from the Wolds runs North and South from Pocklington to Cave. These observations will probably be much extended hereafter.

From the Alps.

The most extraordinary effects of tumultuous waters upon the surface of the land, appear sometimes to surround lofty ranges and groups of mountains. Thus the Mont Blanc group of primary mountains has been rent to pieces by some violent convulsion, and its mingled fragments transported along the *lines* rather than in the actual channels of the Rhone and the Arve into the Valais, along the Lake of Geneva, and up the slopes and through the valleys of the Jura even far into France. By this extraordinary course, blocks of enormous magnitude have been drifted in great numbers on to the tops of mountains, even to the height of 2000 or 3000 feet above the Lake of Geneva, and left there in such abundance as to encumber the land with thousands of extraneous masses. There appears in these collections of blocks a very singular tendency to association in groups and lines. (De Luc.) It is particularly to be remarked that no ordinary action whatever could possibly cover the abrupt mountains of the Saleve and Mont Sion with such immense and numerous masses of these rocks, or transport them across the deep and wide valley of the Rhone to the steep slopes of the Jura. For such powerful effects it will be difficult to assign an adequate cause, and however much influence we may ascribe to the impetuosity even of an uplifted sea possibly cooperating with the disruption of glacier-covered mountains, the phenomenon must ever appear of the most remarkable kind.

We seem to perceive, on a general view of the dispersion of these *erratic blocks* from the Alps, a remarkable relation to the existing valleys. While the Mont Blanc group have yielded fragments to the Rhone and the Arve, the Bernese oberland has supplied the basin of the Aar and the neighbouring part of the Jura; the valley of the Reuss has conveyed the waste of the mountains at its source; blocks from Glaris lie by the Lake of Zurich, and the valley of the Rhine holds the rocks of the Grisons.

The great range of the Jura, opposed to the Alps, and separated from them by the long and wide valley of the Aar prolonged into the Lake of Geneva, has furnished the best opportunity of determining the geographical and other data belonging to the curious problem of the dispersion of these blocks. It is certain that in their course from the Alps the blocks have principally followed the line of the present valleys, since they are found along their sides in greatest plenty, and are collected in most abundance, and lie at the greatest heights, on those parts of the Jura chain which directly face the embouchures of the valleys. Yet this relation to the valleys is of such a kind, that the blocks, instead of being limited to their beds, lie perhaps more plentifully on the hill sides, and intimate a totally different kind of watery action from that of the running streams. Some general convulsions under water, at once elevating the mountains and opening the valleys, and pouring along the floods, may safely be concluded to have caused the phenomena

One of the grandest examples of the form and continuity of diluvial currents is the dispersion to the Southward, across the Baltic, of the primary and transition rocks of Sweden and Norway. Brongniart (*Tableau des Terrains*) has given an excellent view of these phenomena.

From Scandinavia.

The sandy plains of Westphalia, Hanover, Holstein, Zeeland, Mecklenburg, Brandenburg, the coasts and plains of Pomerania, Prussia, and part of Poland far inland between Warsaw and Grodno, and consequently all the low, generally flat, and sandy Countries which border the Baltic and the German Ocean from the Ems and the Weser to the Dwina, and even the Neva, are covered at intervals by these blocks. They are not uniformly dispersed, but collected in particular spaces, and form in the midst of these vast sandy wastes distinct groups, generally elliptical in outline, with the longer axis directed North and South, or toward the Baltic Sea. Bruckner mentions a *trainée* of these blocks in the Northern part of Mecklenburg-Strelitz, which runs from West North-West to East South-East. They are more abundant on hills than in valleys. The largest blocks are most superficial and nearest the tops of the hills. They consist of granites, sienites, transition limestone with trilobites, &c., and other rocks which have the greatest resemblance to the rocks of Sweden; they contain the same *peculiar* minerals, and the same *peculiar* organic remains. Their course from the Scandinavian peninsula is generally from North-East to South-West. On approaching the mountains whence they were dislodged, we find the *number* of the blocks to increase considerably, and on crossing the Sound to Scania, they appear at every step, but the *size* of the blocks is not greater. The mountains of Sweden are not more burdened by loose blocks than is common to such tracts, but the faces of the rocks there appear furrowed and rubbed by the drifting of heavy bodies. The Baltic Sea, which crosses the line of these *trainées of rocks*, appears to have interposed no obstacle to their movement, since the heaps of blocks lie in the same direction on both sides of the water, and the quantities carried over are immense.

Many of the granitic boulders on the coasts of Yorkshire and Norfolk are thought to have come from the same Scandinavian mountains. From observations in England, Dr. Buckland inferred that the general direction of the diluvial currents was from the North-West. In North America, Dr. Bigsby and other observers have observed the prevalent direction to be from the North-West or North-East; the Scandinavian blocks have travelled also from North-East or North North-East. But the waste of the Alps has gone nearly as the valleys run, in all directions; Southward to Italy, Westward to France, Northward to the Rhine, and generally we may be assured that the prevalent direction in any Country has a very close relation to the physical geography of the region.

The degree of attrition of the erratic blocks is various, and generally not so considerable as that of the smaller pebbles which compose the greater part of the diluvial masses.

Inference.

From the preceding data we are warranted in concluding that since the deposition of all or nearly all the marine strata which are seen in our continents, and since the actual land was uplifted from the sea, and shaped into its present leading physical features, large parts of the Earth's surface have been deluged by floods passing in various directions, which removed large quantities of the preconsolidated rocks, and dispersed them over distant Countries, in such abundance, of such magnitude, to such distances, in such directions, and to such altitudes, as to preclude the possibility of explaining the phenomenon by the action of *actual streams*, flowing in the ordinary course of nature, or deviating in any possible manner over the surface of the Earth, or by the bursting of lakes, however situated or circumstanced. For neither streams nor bursting lakes could possibly transport the Shap Fell granite to Flamborough Head, nor drive the sienites of Sweden into the heart of Poland.

Gravel deposits.

For the sake of exhibiting decided proofs of the powerful action of the diluvial waters, we have insisted much on the transport of large blocks of recognisable rocks; but it must not be imagined that such blocks of such magnitude compose the whole or the greater part of the diluvial deposits. These consist, in fact, of the detritus and fragments of every sort of rock, and of all sizes, from the giant blocks on the Jura to the finest sand and sediment. The Eastern coasts of England, in Essex, Norfolk, and Yorkshire, are principally occupied by diluvial cliffs of clay, with interspersed pebbles and blocks, and irregular layers of gravel and sand. These deposits cover large tracts in Yorkshire, Lincolnshire, Norfolk, Suffolk, Essex, &c. In the Midland Counties, gravel, containing in some places abundance of chalk flints, and in other situations pebbles from the Lickey Hill, is very common, and particular valleys quantities of oolitic gravel. It is generally observable that the most abundant portions of the deposits may be traced to the neighbouring ranges of hills, as the chalk of Holderness, Faldingworth, and Huntingdon, to the neighbouring wolds, the sandstones of the vale of York to the Western moorlands, and the quartz pebbles of Warwickshire to the Lickey Hill, but with them generally lie fragments from more distant sources.

Animal population at the time,

We now proceed to inquire what was the condition of the land over which the diluvial currents flowed, with respect to its animal population. That it was inhabited, and very extensively so, in many districts wasted by these floods, is evident from the really immense quantity and variety of bones of quadrupeds lying in gravel pits, clay cliffs, and other diluvial accumulations, or buried in caverns during and previous to that period of convulsion.

To mention all the known localities for diluvial masses from which bones of elephant, rhinoceros, horse, ox, deer, and a variety of other quadrupeds have been obtained, would be to form a gazetteer of Europe, Siberia, and North America. There is hardly a County in England where some remains of this kind have not been obtained at many places, and they are equally abundant in France, Germany, Italy, &c.

Exactly as at the present day the bed of a river envelopes the shells that perish in its waters, with the bones of animals accidentally lodged there, so the diluvial floods buried in the detritus of the land remains of the then existing organized creation. These remains enable us to say what races of animals were living upon the Earth at and previous to the time when those parts of it were overwhelmed; and if upon examination it be found that these animals were of peculiar types of conformation, that they did not begin to exist till a certain epoch, nor continue to live after another epoch, the period of their existence is a *zoological era* as distinct as any other disclosed to us by examination into the long series of periods during which organic beings have existed upon the Earth.

In illustrating this magnificent subject from the materials furnished by the researches of Cuvier and Buckland, we shall first present the evidence furnished by diluvial gravel, clay, sand, and other unquestionable deposits of the turbulent era alluded to; and afterwards add some results deducible from examination of caverns, the period of the occupation of which will be naturally determined by comparing their zoological contents with those of gravel pits, &c.

The following are some of the animals that have been discovered in these diluvial deposits.

Pachydermata.

Elephas primigenius.
Mastodon maximus, &c.
Hippopotamus major.
Chœropotamus.
Rhinoceros tichorhinus, &c.
Tapir giganteus.
Sus fossilis.

Solipeda.

Equus fossilis.

Edentata.

Megalonyx.
Megatherium, two species.
Manis giganteus.

Mostly congeneric with those now living;

The most striking general inference derivable from inspection of the preceding and more extended lists, as contrasted with all the catalogues of the earlier animals, is the almost complete identity of the genera with some of those which now exist. Even in the tertiary system, though the quadrupedal population of Europe had become considerable, and the circumstances of their existence in several respects closely analogous to what obtain at present, the genera were for the most part wholly different. Here they are for the most part the same.

The species, however, of the zoological era under consideration were mostly different from the existing races, some of greater magnitude, others of different proportions, all distinguishable by more or less remarkable peculiarities of their bony remains. Yet these distinctions are often minute, and unless the question of the amount of possible change induced on the animal frame by long time and varying circumstances could be more exactly appreciated, it may perhaps always admit of a slight doubt whether the distinctions alluded to be characteristic of the species of animals, or of the circumstances of their existence. However, *for all* purposes of geological induction, the distinctions being constant are assumed to be specific.

Among the species found in caves, fissures, and breccia, referred to the same era, are the following.

Pachydermata.

Elephas primigenius, &c.
Hippopotamus major.
Rhinoceros tichorhinus, &c.
Chœropotamus.
Sus fossilis.

Solipeda.

Equus fossilis.

Ruminantia.

Cervus euryceros, &c.
Bos, urus, antilope.

Carnivora.

Felis spelæa, &c.
Hyæna spelæa, &c.
Polecat.
Weasel.
Gulo spelæus.
Wolf.
Fox.
Ursus spelæus.
cultridens, &c.

Rodentia.

Arvicola fossilis media.
minor.
Rat.
Lagomys, &c.
Hare, rabbit, &c.
Beaver.

From the general analogy between these two lists, from the prevalence in each of elephants, rhinoceros, hippopotamus, felis, hyæna, and bears, in Countries where at present not a single animal of such genera is known to exist, there seems every good reason to admit them as belonging to the same zoological era, which M. Omalius D'Halloy has, not inconveniently, called the mastozootic era. But all investigations concerning gravel and other diluvial deposits, prove indubitably that this era is exactly that which ended with the diluvial system of deposits. We may, therefore, venture in the following investigations to class together the remains of mammalia found in caves, fissures, breccia, gravel, clay, &c. as characteristic of a period of some duration, terminated in each district by great inundations, and equally capable of furnishing evidence concerning the then state of the Earth. It is not meant by this arrangement to pronounce at all concerning the question, yet very insufficiently examined, of the partial contemporaneity of the palæotherian and mastozootic races of animals in Europe.

Lived in Countries where their bones are found.

The first general result which we shall venture to draw from this combined evidence is, that the animals whose remains are found in diluvial gravel and other superficial accumulations, or in limestone caves and fissures, or in ferruginous breccia, lived near or on the spots where their bones are found. This important inference might be safely deduced from the ordinary circumstances under which fossil bones are found in superficial gravel, &c., since in these cases they are little worn, though lying amongst fragments of rocks rounded to pebbles, and often remain entire, or with no other injury than that occasioned by the effects of the atmosphere. Thus, the horns of a stag, scarcely in the smallest degree injured, have been obtained from the diluvium of the vale of Pickering, the long tusks of an elephant from that of Holderness and Essex. This conclusion might, perhaps with equal certainty, be rested upon the occasional finding of the bones of elephants and rhinoceros, and other "antediluvian" species, in marl pits under gravel, in company with shells now existing in the neighbourhood, of which some indications occur in Cuvier's celebrated Work the *Ossemens Fossiles*, and a more distinct case, at Market Weighton in Yorkshire, has been recorded by Mr. Dikes of Hull, and several members of the Yorkshire Philosophical Society. For in this case the bones of extinct and the shells of existing species of animals lay pellmell together, and the native locality of one must inevitably be ascribed to the other.

But the case becomes certainly stronger, when we take into view the history of the caverns, fissures, and breccia, containing bones; for these afford us not only reason to conclude that certain animals lived in definite regions at a particular era, but display many of their habits of life and accidents to which the nature of the country exposed them. Those who desire to follow at length the detailed history of caves and osseous breccia must be referred to the luminous pages of Buckland, (*Reliquiæ Diluvianæ,*) and that imperishable monument of genius, the *Ossemens Fossiles* of Cuvier. We shall here present a simple analysis of the leading *results* of their inquiries bearing on the subject before us.

Caverns and fissures containing bones, however preserved, and of whatever kinds these are, present some important characters in common.

Ossiferous caverns, how situated.

(1.) In the first place they are, we believe, always situated in limestone, very generally in stratified limestone, though this character is sometimes denied to the dolomitic limestone of the Mediterranean shores. This circumstance has, however, apparently no relation whatever to the accident of the caves containing bones, but is merely a general fact characteristic of limestone; for in this kind of rock nearly all the caverns, grottoes, and remarkable natural fissures in the World are situated. And as far as we have observed, there is no reason whatever in speculations on the *origin of the bone caverns and fissures* to exclude those of similar forms in which no bones occur.

(2.) This being the case, we may remark further, that though in some cases the existence of the cavern may be thought to be connected with dislocations of the strata, as at Greenhow Hill in Yorkshire, yet this is rather the rare exception than the general rule. The carboniferous limestone is full of caverns, yet not more so where numerous slips and veins divide it than in other places. Veins of lead ore hardly ever lead to these caverns, and it is a matter of general remark, that though the strata may be disturbed near them, the disturbance has little to do with the caverns.

(3.) Most caverns, whatever be the character of their floor, assume at intervals along their length, the appearances of a great fissure in the rocks. This circumstance must have been often observed by those familiar with the caves of Somersetshire, Derbyshire, and Yorkshire, and is recognised even in that least favourable example, Kirkdale Cave, which in its nearly level course keeps its floor nearly on one particular bed of the rock, but occasionally opens upwards into narrow irregular expansions or fissures. The fissures filled with breccia may, in fact, be often regarded as exposed caves, and resemble them in all essential circumstances.

(4.) Very few of these cavities in the rocks are entirely free on their sides and roof from remarkable depressions and cavities, like those produced on limestone by currents of water, or the slow consuming agency of the atmosphere. Many of them which now convey water, and are not incrusted with stalagmite, as the Peak Cavern in Derbyshire, show this sort of watery erosion so strongly as to impress most beholders with a conviction that the whole was excavated by the running stream.

(5.) Several writers, in particular Brongniart, have attempted to show that mere water has no effect in eroding rocks. This may, perhaps, be true of the *oxide of hydrogen*, but is certainly not a correct account of the effect of common water, and particularly of *water containing carbonic acid*, and traversing limestone rocks. The innumerable petrifying springs of limestone Countries at once demonstrate the inaccuracy of this reasoning. The very rain from the heavens eats away these stones rapidly. The springs which issue from limestone generally contain carbonate of lime, and most of them yield a large quantity of free carbonic acid upon exposure to the air.

How formed.

(6.) Those accustomed to underground works know it as a familiar fact, that the water which is absorbed by dry limestone land, takes particular channels through the rocks, down the joints, and along certain fissures. Every limestone hill in the carboniferous district of the North of England, shows in its *swallows* and *moor pits* the erosive power of the atmospheric water. We shall, therefore, venture from all these considerations to maintain the enlargement or excavation of these caverns to be principally owing to the subterranean passage of water charged with carbonic acid, the direction of this water, and its power of erosion, being favoured by fissures and other causes. If the altered drainage and other circumstances of a country so far change the course of the water as to leave these subterranean channels almost dry, the small quantity of moisture continuing to arrive, may slowly deposit stalagmite over the surfaces formerly eroded, and the cave change its appearance altogether. An accidental inrush of water from another source may deposit mud or pebbles, and this be also covered up by another layer of stalagmite.

It is no great objection to this view, that the cavities are sometimes exceedingly irregular, for water in its subterranean course must follow the original cracks of the rocks. Indeed, upon a review of this matter, that very irregularity may perhaps be thought an argument in favour of the mode of origin here suggested.

The most remarkable ossiferous caverns in England are Kirkdale Cave near Kirby Moorside in Yorkshire, the Dream cavern near Wirksworth in Derbyshire, Banwell Cave in the Mendip Hills, Kent's Hole near Torquay, Oreston near Plymouth, and Paviland near Swansea; in Germany, the slopes of the Harz mountains give us the caves of Baumann, of Biel, and of Schwarzfeld. Between the Harz and Franconia is the Bear Cavern of Glucksbrunn; the Jura formation near Baireuth is celebrated for the rich associated caverns of Gailenreuth, Schænestein, Brunnenstein, Holeberg, Wieserloch, Geissloch, Wunderhohle, Rabenstein, Kuhloch, Zahnloch, Schneiderloch, Rewig, &c. In Westphalia the same oolitic formation has the caves of Kluterhohle, and Sundwich. The Caves of Adelsburg in Carniola and the Dragons' Caves in Hungary have also yielded bones. In France, instructed by Dr. Buckland's researches, two caverns, rich with bones, have been described by M. Thirria near Vesoul, and several others near Montpellier and Narbonne by Marcel de Serres, Tournal, Christol, &c. and one near Miremont by M. de la Noue.

Osseous breccia appears singularly connected with the coasts of the Mediterranean. It occurs at Gibraltar, in Languedoc, and at several other points in the South of France, at Antibes, Nice, Pisa, Cape Palinurus, North of Bastia, (Corsica,) Cagliari, (Sardinia,) Maridolce, (Sicily,) in Dalmatia, Aragon, &c. Ferruginous breccia, in which bones are associated with pisolitic iron ore, occurs in Wurtemberg, and in Carniola in Jura limestone.

How filled with bones.

In some of these caves hyænas lived and dragged into them for food the bones of other animals existing in the vicinity; bears died in others; some were filled by the accidental falling in of browsing quadrupeds, and others heaped with a mixture of bones, mud, and pebbles brought by general or local floods on the surface. We shall give an abstract of the characteristic facts attending each of these cases.

Kirkdale Cave.

Kirkdale Cave is one of the most remarkable instances of ossiferous cavities known in England, both from the number of species and abundance of the bones of quadrupeds found there, their state of conservation, and other attendant circumstances. The entrance of this cave is on the side of a narrow valley 30 feet above the stream in a nearly level and perfectly undisturbed bed of coralline oolite. It had a sort of vestibule, much larger than the interior windings of the cave, and in this, according to Mr. Salmond, lay a considerable proportion of the large bones of elephant, rhinoceros, &c. Beyond this was a STEP in the floor of the thickness of one bed of limestone, leading to the interior recesses, which follow an irregular line, occasionally rising to the height of 14 feet, but generally under 4 feet, and about the same breadth, but liable to contractions in both their measures. The floor was generally overspread and its inequalities filled up by a layer of mud, of calcareo-argillaceous substance, such as might be supposed derivable from the joints and partings of the limestone. In some places the mud was more coarse and sandy. Stalagmite in considerable quantity had dripped from the roof, incrusted the sides, and covered like a sheet the layer of mud rising upon its surface into mamillary tubercles.

In the mud, and protruding occasionally through its stalagmitic covering, lay the bones of six or seven *carnivora*, hyæna, tiger, or lion, bear, wolf, fox, and weasel; three *pachydermata, viz.* elephant, rhinoceros, hippopotamus, the horse; four *ruminantia*, ox, and three kinds of deer; four *rodentia*, hare, rabbit, water rat, mouse; beside five birds, raven, pigeon, lark, duck, and a bird of the size of a thrush.

The bones were scattered over this long area, "as over a dog kennel," almost universally broken to pieces, not as if by common fracture, but by violent biting and gnawing: marks of teeth are discernible on many, exactly like those left by living hyænas on similar bones submitted to their jaws. Hyænas' teeth in great numbers, of all ages, milk teeth, shed teeth, and worn to stumps in the jaws of the animal, abounded in the cave, besides a considerable quantity of osseous fecal matter, like that of the modern hyæna. From these data, most of which may be verified on the numerous specimens extracted from the cave, Dr. Buckland infers, that hyænas were for a long period the undisputed tenants of this den, lived in it for many generations, dragged into it for food, piecemeal, the bodies of animals then living in the neighbourhood, and were finally dispossessed of their hold by an irruption of water which let fall the muddy sediment now enveloping the bones. The ordinary action of the water passing through the calcareous rock then covered the whole with stalagmite, and closed up the bones from the destructive agency of moisture and air. This accounts for the conservation of their gelatine. Few conclusions of this precise nature appear better supported by the facts of the case, and when we reflect on the remarkable analogy, in almost all points concerning the state and conservation of the bones, of the cavern at Torquay called Kent's Hole, and contrast these particulars of the *hyæna dens* with those of the *ox caves* in Mendip, we shall feel a full conviction that Dr. Buckland's bold theory is a true interpretation of Nature.

Cave of Kühloch.

The caves of Franconia appeared to Dr. Buckland to have been tenanted by bears which died in the retired parts, and were there mixed more or less with sediment and pebbles brought by subsequent diluvial floods, and the whole covered over by a stalagmitic crust formed in the usual way. The cavern of Gailenreuth is perhaps the most magnificent example of this doctrine; but that at Kühloch presents some peculiarities of a very interesting kind. "It is literally true that in this single cavern (the size and proportions of which are nearly equal to the interior of a large church) there are hundreds of cart-loads of black animal dust entirely covering the whole floor, to a depth which must average at least six feet, and which, if we multiply this depth by the length and breadth of the cavern, will be found to exceed 5000 cubic feet. The whole of this mass has been again and again dug over in search of teeth and bones which it still contains abundantly, though in broken fragments. The state of these is very different from that of the bones we find in any other caverns, being of a black or more properly speaking dark umber colour throughout, and many of them readily crumbling under the finger into a soft dark powder resembling mummy powder, and being of the same nature with the black earth in which they are imbedded. "The quantity of animal earth accumulated on this floor," continues Dr. Buckland, "is the most surprising and the only thing of the kind I ever witnessed; and many hundred, I may say thousand individuals must have contributed their remains to make up this appalling mass of death. It seems in great part to be derived from comminuted and pulverized bones; for the fleshy parts of animals produce by decomposition so small a quantity of permanent earthy residuum, that we must seek for the origin of this mass principally in decayed bones. The cave is so dry that the black earth lies in the state of loose powder and rises in dust under the feet: it also retains so large a proportion of its original animal matter, that it is occasionally used by the peasants as an enriching manure for the adjacent meadows." This cave is entered by a lofty arch, above the river Erbach, expands within both in height and breadth, and terminates in two chambers closed at the end. No fissures enter this cave, and it has no other exit than the entrance above named, except a very small passage to the same valley. These circumstances are considered by Dr. Buckland to explain the absence of diluvial accumulations in this cave. There is no appearance of either stalagmite or stalactite having ever existed in this cavern.

Mendip

Dr. Buckland's views concerning the ancient occupation of hyænas and bears of the caves of Kirkdale and Franconia, derive much elucidation from the discoveries of other caverns in which the animal remains appear to have been accumulated in a different manner. We shall mention those of Hutton in the Mendip Hills, and of Ouston near Plymouth; the former disclosed by ochre works, the latter by quarrying for limestone. The ochre of Mendip Hills appears, in some cases, to be derived from the decomposed strata of the vicinity, and deposited in caves and fissures of the limestone, either by water continually passing downwards by filtration, or by some more transient and violent operation. In pursuing one of these mines of ochre near the village of Hutton, bones of many animals were discovered, and the circumstances were examined by the Rev. Mr. Catcott, from whose manuscript Mr. Conybeare has drawn up a clear account of this remarkable occurrence. The elevation of the ochre pit was 300 to 400 feet above the sea. "The ochre was pursued through fissures in the limestone occasionally expanding into large cavernous chambers, their range being in a steep descent and almost perpendicular. In opening the pits the workmen, after removing 18 inches of vegetable mould and 4 feet of rubbly ochre, came to a fissure in the limestone rock, about 18 inches broad and 4 feet long. This was filled with good ochre, but contained no bones: it continued to the depth of 8 yards, and then opened into a cavern about 20 feet square and 4 high; the floor of this cave consisted of good ochre, strewed on the surface of which were multitudes of white bones, which were also found dispersed through the interior of the ochreous mass. In the centre of this chamber a large stalagmite was suspended from the roof, and beneath a similar mass rose from the floor almost touching it; in one of the side walls was an opening about 3 feet square, which conducted, through a passage 18 yards in length, to a second cavern 10 yards in length and 5 in breadth, both the passage and cavern being filled with ochre and bones. Another passage, about 6 feet square, branched off laterally from this chamber about 4 yards below its entrance; this continued nearly on the same level for 18 yards; it was filled by *rubbly ochre, fragments of limestone, and lead ore confusedly mixed together; many large bones occurring in the mass*, among which four magnificent teeth of an elephant were found. In the second chamber, immediately beyond the entrance of the branch just described, there appeared a large deep opening, tending perpendicularly downwards, filled with the same congeries of rubble, ochre, bones, &c: this was cleared to the depth of 5 yards; this point being the deepest part of the workings was estimated at about 36 yards beneath the surface of the hill." (*Reliq. Diluv.*) The bones found in Hutton Hole belong to elephant, rhinoceros, ox, horse, deer, hyæna, bear, a nearly complete skeleton of a fox, hog, and some gnawing animal.

Oreston Caves.

Three deposits of bones at Oreston, near Plymouth, have been detected by Mr. Whidby during the removal of the entire mass of a hill of transition limestone for the construction of the Breakwater. The first deposit (1817) lay in a cavern 15 feet wide, 12 high, and 45 long, and about 4 feet above high-water mark. This cavern was filled with solid clay, in which teeth and bones of rhinoceros were embedded. The second discovery (1820) was of a smaller cavern, distant 120 yards from the former, one foot high, 18 wide, and 20 long, and 8 feet above high-water mark. But the greatest extent of subterranean cavities was exposed in 1822, by the intersection of apertures in the middle of the limestone, containing an immense deposit of bones and teeth imbedded in clay. Dr. Buckland describes in a very graphic manner the irregular branching or insulated fissures and caverns which were at this time laid open in an artificial cliff 90 feet high, their various direction, loamy contents, and relation to similar cavities not containing bones in the neighbouring limestone cliffs. He remarks that the fissures and caverns are so connected, so often confluent and inosculating with each other, and so identical in their contents, that there appears to be no difference as to the time and manner in which they were filled. In many of those which are nearly vertical, the communication is obvious, but those which pass obliquely, and consequently seldom lie in the plane of the cliff, may *appear* to close upwards. In almost all the cavities there occurs a deposit of mud and sand, and angular fragments of limestone; these substances sometimes entirely fill up the lower chambers, and are lodged in various proportions on the shelves and ledges and in lateral hollows of the middle and upper regions. In one large vault it is sorted into laminæ; sometimes it is interspersed with extraneous fragments of quartz and clay slate; stalagmite sometimes invests it; in some few spots were balls of iron-stone, and concretions of ochre formed in the clay; in others was a considerable quantity of manganese ore, sometimes in concentrically coated balls. The bones collected in the Oreston caverns and fissures belong to hyæna, tiger, wolf, fox, horse, ox, deer. The bones of the horse predominated; those of ox and deer were also abundant.

We may admit, without hesitation, that these caverns and fissures at Oreston were filled with this mingled mass of earthy, stony, bony, and metallic matters, by aqueous action; and there seems no good reason to doubt that partly in this manner, and partly by the accidental falling of quadrupeds into open fissures of the limestone, many other caves in Somersetshire, Derbyshire, &c. have been stored with their animal remains.

Osseous breccia of the Mediterranean.

From such cavernous fissures, filled with mingled fragmentary masses, as those of Oreston, there is hardly a step to the fissures or caves containing ossiferous breccia at so many points around the Mediterranean Sea. Almost every limestone rock, wherever its interior structure can be seen on the sea-coast, in ravines, in mines, is found to be traversed by fissures and excavated in caverns: it was therefore to be expected that such should be exposed in abundance in the calcareous precipices of the Northern shore of the Mediterranean. But it is very remarkable that they should be in those regions so generally productive of bones; that these should so generally be found in a reddish-coloured loamy breccia, holding fragments of the neighbouring rock, helices, and other spoils of the land; and that no marine production whatever should be found mingled with the mass, though, as at Santo Ciro, near Palermo, (*Geological Proceedings*, 1833,) there be proofs of the marine submersion of the actual cave, before the introduction of the bony breccia. There is clearly no necessary relation between the existence of these ossiferous cavities and the proximity of the sea; in many cases their exposure may be owing to the waste of the coast, but in others it must be mainly ascribed to the convulsive elevation of the land at some ancient period. In all cases the production of caverns and fissures in the rocks is the work of causes acting during periods long anterior to those when the animal remains were introduced. Thousands of cavities have been produced in the rocks, and filled with mineral treasures, and buried beneath vast depths of consolidated strata, of very high antiquity; such of them as were by any causes exposed at the surface, have been filled with clay, or heaped with fragments of rock, and in the great majority of instances lined with calcareous spar, and in Countries which were then inhabited by quadrupeds some have been partly filled by bones. The Geological era, when the latter occurrence happened, is rendered definite only by a rigid anatomical examination of the bones; and by this Cuvier has taught us that we may confidently refer the great majority of the quadrupedal remains, whether found in gravel on the surface, in the mud, gravel, breccia, or stalagmite, or on the naked floor of subterranean caverns, to one zoological period. In general, the most abundant remains in the ossiferous breccia of the Mediterranean shores belong to the orders ruminantia and rodentia; bones of ursine, feline, and canine animals, as well as those of hippopotamus and elephant, are rare. This is exactly what should happen upon the supposition that the bones in the fissures were derived chiefly from animals which fell into them, for these naturally should consist principally of herbivorous tribes. The presence of land shells, of fragments of the neighbouring rocks, the abundant interlacement of stalagmitical carbonate of lime, tends exactly to the same conclusion; and even the redness of the breccia of Gibraltar, Cette, &c., is probably owing to the ferruginous nature of the neighbouring rocks. The influence of local causes is thus clearly indicated, and in the opinion of Cuvier, these have operated through considerable periods, so that the bones and fragments of rocks fell successively into the cavity, and the calcareous cement was gradually accumulated. If, in addition, we suppose, with Dr. Buckland, that these same cavities have since undergone the action of moving water, which might drift in heaps the fragmented bones and stones, and mix with them loam and occasionally pebbles, all the phenomena seem naturally explained, and the theory of the ossiferous breccia becomes connected with that of the proper cavern deposits. For particulars respecting the ossiferous breccia of Gibraltar, Cette, Antibes, Nice, Pisa, Cape Palinurus, Corsica, Sardinia, Sicily, Dalmatia, Cerigo, Aragon, and the Veronese, we must refer to Cuvier's admirable *Ossemens Fossiles*, tom. iv.

Climate of the Northern regions in the Elephantoidal era.

As from the facts previously related, no doubt whatever can remain that in the "diluvial" period, and for a long time previous, there existed in Europe elephants, rhinoceros, hippopotamus, lions, and hyænas, besides bears, the glutton, wolves, foxes, the horse, oxen, the urus, deer, beavers, hares, rabbits, water-rats, &c., we are presented with a problem of considerable interest relating to the state of the climate at that period. The most abundant, perhaps, and most generally diffused of all these remains are those of the elephant and rhinoceros; though in particular cases, bears or hyænas fill whole caves, and the horse, ox, and urus are very plentiful in gravel and marl. So many animal remains of genera now exclusively confined to hot climates, have induced many Geologists to conclude that the Northern regions of the Globe were at that time much hotter, and that their total extinction was occasioned by a sudden refrigeration of the climate. On the other hand, the glutton, the urus, wolves, foxes, bears, horses, and large horned deer, and beavers, appear as characteristic of cold or temperate climates, and furnish arguments for the doctrine that the animals resembling those now living in tropical regions, were fitted by some peculiarity of constitution to support the rigours of the Northern zone. These statements are so equally balanced, and the authors who support them so respectable, that no impartial inquirer can pronounce between them without further evidence. This evidence must be of a particular kind. It will be of little use to add to the number of animals on either list; and as the *species* are *different* from those now in existence, the relative power of adaptation to climate of their several living analogues will not be sufficient to settle the point. We must find the remains of some of these animals, in such condition, or accompanied by such collateral circumstances, as to characterise the climate independently of the generic relations of the animals.

vidence n this subject.

Two cases coming within these conditions are known to Geologists, of so distinct a kind, and leading so positively to the same conclusion, as to leave little room for further discussion. The first is the instance of an elephant, of the same species precisely as that usual in diluvial accumulations, being found in 1804, enclosed in solid ice, at the mouth of the Lena, where that Siberian river flows into the Arctic Sea. It was a perfect animal, with tusks in the jaws, and had evidently been entombed in its icy sepulchre immediately after death, for the flesh of its huge body was not decayed, but actually furnished a feast to the wolves and bears of the coast; the skin remained entire, and its whole surface was covered with *hair of two kinds*, one shorter and finer near the body, the other coarse and bristly, and even sixteen inches long. It is to be regretted that the difficult circumstances of the country did not permit Mr. Adams to examine minutely the anatomy of this specimen, thus wonderfully preserved through the fluctuations of ages; but the skeleton, mounted at St. Petersburg, furnishes sufficient characters to prove its perfect agreement with the fossil, and its distinctness from either of the living elephants. Here then is a plain proof that the fossil elephant was fitted, by an appropriate clothing, to withstand the occasional cold of a high Northern latitude, not perhaps to exist on the shores of the Icy sea, but to inhabit about the sources of the Siberian rivers, and over the whole extent of Europe and a part of North America. The North coast of America, as well as that of Siberia, encloses abundance of the remains of these elephants in cliffs of frozen mud. (Capt. Beechey.)

The conclusion from this fact is rendered still more decisive by the discovery, in 1770, of the fossil rhinoceros tichorhinus, under the same extraordinary circumstances of preservation of flesh, on the banks of the Wiluji, which falls into the Lena below Jakoufgk, and its body was likewise *covered with hair*.

Dr. Buckland's conclusion of some remarkable catastrophe and sudden refrigeration of the Siberian regions and the borders of North America, near Behring's Straits, seems to offer a reasonable explanation of the extraordinary preservation of these remains, which besides may have been drifted from their original seats Northwards.

The second case is the discovery together in the same marl pit, connected with gravel deposits, near Market Weighton, in Yorkshire, of the remains of elephant, rhinoceros, lion, wolf, horse, urus, ox, deer, &c., species all or nearly all extinct, with thirteen species of land, marsh, and fresh-water shells now living in the neighbourhood. Now as hardly any animals are more remarkably limited in climate, and restrained by local circumstances, than the molluscous tribes of the land and fresh waters, as the number of the species here discovered is considerable, and their identity altogether certain, without a single extraneous species, it is a safe conclusion, that the climate in which they lived was that which England and the central parts of Europe now enjoy; for such mollusca become mixed with other races on approaching the Mediterranean, and many of them cease to exist in the colder latitudes of Northern Europe. The same conclusions result from the examinations of that remarkable deposit called "Loess," in the valley of the Rhine, where the extinct elephants and rhinoceros lie with many existing land shells. (Horner.) Hence we conclude, with confidence, that the antediluvian climate of the Northern parts of the Globe was nearly the same that it is at present; and it is no great objection to this view, that the banks of the Frozen Sea will not now feed an elephant, because, in the first place, it is not yet proved that the elephants were not drifted by the long Siberian rivers to their frozen mouths: and secondly, our conclusion is for a temperate or cold, not frigid climate, as distinguished from the torrid climate, to which some Geologists would unmercifully subject these animals in their warm Winter dress.

Other problems.

Nearly all the propositions that we have endeavoured to establish concerning the important subject of diluvial accumulations will be admitted by theorists of every order. That the Earth has been covered over a large extent, since the completion of nearly its whole apparent series of successive marine formations, by tumultuous floods of water, powerful enough to dislodge and transport, hundreds of miles from their native sites, huge blocks and fragments of rocks, and to destroy the races of animals then living in those Countries, and to produce considerable changes in Physical Geography, is a fundamental doctrine of modern Geology. But questions of considerable difficulty, which might perhaps have been postponed to a later period of the investigation, if the Science had been permitted to follow its own secure course of observation and induction, are forced upon our attention by the anticipations of theory, and the premature anxiety felt, even by writers on Geology, to establish parallels of time between the Geological datum of the destruction of certain land-animals and the Noachian Deluge.

We have shown that these diluvial floods were very extensive, but we are required to answer further whether they were *universal*. We have proved them to have belonged to a certain limited zoological era; but we are asked, were they *simultaneous* over the globe? We have admitted that they have effected changes in the physical features of the Earth's surface, but we are called upon to state whether *valleys* were excavated by their agency.

This is the place to discuss the two former questions; the latter, though often mixed up with the others, will admit of clearer solution by first examining the action of existing causes in modifying the surface of the Earth.

Extent of the phenomena.

The doctrine of the *universality* of the diluvial currents, was adopted by Geologists, according to their interpretation of the connection between Geology and the Hebrew Scriptures, long before they had acquired the power of clearly tracing the effects of such currents across their own hills and valleys; and after Mr. Smith had fixed some of the leading characters of the diluvial detritus in England, they were hastily, by anticipation, applied even to Countries never visited by any observer. Subsequent researches have to a certain extent justified this boldness; and the discoveries of Buckland and Cuvier, by fixing zoological characters for the diluvial periods, have harmonized the results into a system. But it is unsafe at present to venture such a doctrine as the universality of the diluvial currents, even upon the admission that their powerful traces are recognised over nearly the whole Northern hemisphere. If, indeed, it should eventually be proved, that diluvial currents have constantly followed upon the elevation of large tracts of land above the sea, their universality might be safely inferred, since nothing can be more clear than the former submersion of all our continents. But this would not satisfy all the conditions of the problem; as in diluvial gravel and caverns so closed there would be no reason to expect the bones of land-animals, and it is a matter of notoriety that the elevation of land above the sea, instead of being confined to the mastozootic era, has proceeded at intervals through the whole Geological period.

It must, indeed, be owned that many mountain ranges were uplifted at the periods alluded to, but we dare not so far deviate from the method of observation and induction which has raised Geology to its elevated rank among the Sciences, as to assume universal inundations of the Globe, to follow confessedly partial disturbances of the bed of the Ocean. On this, as on many other questions, we must appeal to further observation.

Length of the diluvial period.

The doctrine of *simultaneity* of diluvial currents over the Globe, was introduced by the same desire to accommodate Geological theory to the ordinary interpretation of the Mosaic record, and involves considerations of great difficulty. To determine whether diluvial phenomena are traceable over a greater or less extent of the surface of the Earth is the work of observation. To settle the date of these phenomena with reference to one another is a very nice and difficult subject of analysis and inference. Even if it were the fact that the diluvial detritus in different Countries was scattered by the devious currents of one simultaneous inundation, it is doubtful whether satisfactory Geological evidence could be collected to *prove* this. No single deluge of such vast extent has been disclosed by investigations of the phenomena of earlier date; we see no agencies, either cosmical or terrestrial, likely to occasion it now; it cannot, therefore, be *assumed*, as a natural phenomenon, without violation of the rules of Philosophy.

But though, strictly speaking, *the* question of the simultaneity of the diluvial catastrophes in different regions is inadmissible in the present state of our knowledge, we may modify the inquiry so as to bring it within the scope of examination. Let us inquire if the diluvial phenomena of all Countries in which they have been observed, have so much of a common character as to point to the same *kind* of cause, so much of a common direction as to be assignable to causes having *the same local origin*, and are accompanied by such collateral circumstances as to be limited within *an assignable period of time*. The first point is already answered in the affirmative by all the preceding observations; on the second point, we may observe that a considerable number of observations indicate a prevalent direction of currents from the North, but many others appear to refer the local origin of the currents to the neighbouring mountains. The third part of the inquiry has also been met in part by the history of the animal remains in *the* diluvial and antediluvial deposits; for these clearly belong to a limited zoological period, and as this period appears to have been terminated in each district by the diluvial catastrophes, we are justified in believing that the time during which these turbulent waters flowed was comparatively short. To the same conclusion we must necessarily arrive, from a comparison of the diluvial disturbances with those of older Geological periods.

But short as this period was, we are able to divide its characteristic phenomena into successive stages. There are few parts of England, where the diluvial masses do not consist of more than one kind of deposit, derived from a current in one direction. On the coast of Yorkshire the general base of the whole diluvium is a thick mass of clay, with heaps of fragments of rocks derived from Cumbria and North-Western Yorkshire scattered through it. In some places this rests upon water-moved chalk and flints; in others it is surmounted by beds of gravel and sand, which are themselves, near Bridlington, covered by thick layers of chalk and flints from the neighbouring wolds. But we must be careful not to infer from this and similar facts more than they will bear. The lapse of time is here proved, but as no deposit intervenes implying that the time was considerable, as the lower diluvium is not water-furrowed to admit the upper, as the same characteristic animal remains are found in several portions of the deposit, it is possible that all these successive diluvial masses might be brought by the varying impetus of one continuous or intermitting general convulsion. De Beaumont, from his admirable survey of the Alps, infers with great probability that the diluvium around these mountains belongs to two distinct periods, and was occasioned by two separate convulsions affecting the Alps. By the former convulsion, which elevated the Western Alps from Dauphiné to Mont Blanc, prodigious quantities of débris rolled off to the West, and by the second convulsion, which elevated the Eastern Alps from Mont Blanc to Vienna, the old diluvium was dislocated, and floods were occasioned, which transported a great quantity of materials over the detritus of the former period. Here, also, we must be cautious in the inference. That *some intervals* happened amidst the diluvial disturbances, that the diluvium is of *unequal antiquity* is clearly proved; but nothing has yet been established contrary to the general view of this subject, which we have before suggested, *viz.* that the diluvial phenomena were produced during *a comparatively short period* of convulsion of the land, and consequent agitation of the sea, ensuing upon the completion of all, or nearly all the marine strata, now apparent above the sea, and subsequent to the habitation of at least the flatter regions of the Earth by various races of quadrupeds now extinct. This is all that can be safely asserted in the present state of Geology.

Geological monuments of the existence of Man.

In all the periods of time which elapsed during the formation of the stratified rocks, there is no evidence that Man was a dweller on this Globe. Not in the most recent of the tertiary strata, neither in the littoral nor in the lacustrine deposits of that period, have any traces of Man or his works been perceived. This ought in no degree to surprise us, for all the animals and plants of that and earlier periods were *parts of an earlier system* of organized nature. But it appears something extraordinary that bones of men and vestiges of human art should have been so rarely found in any of the ascertained deposits of the diluvial era, except under dubious or explanatory circumstances, since at that time the earth had assumed its present form and appearance, and was inhabited by races of quadrupeds which, if not specifically the same, were, for the most part, closely analogous to those which now live; in particular, the horse and domestic cattle, animals so singularly serviceable to and dependent on Man, existed in great plenty in the Northern zones, and, therefore, the *present system* of organized nature, of which Man is the head, may be said to have commenced.

That the bones of men are as durable as those of quadrupeds, is established by comparisons made on fields of battle, and, therefore, if he lived with the mastozootic quadrupeds, his remains should, under some circumstances or other, be found mixed with theirs. Dragged into a den by the prowling hyæna, or accidentally lost in a fissure, or overwhelmed by waves and buried in diluvium, we should frequently meet with the bones of our ancestors. Old writers, who saw in every thing only the traces of a general deluge, are full of discoveries of the bones of *men;* but modern anatomy has assigned them to their true analogies, the *elephant, salamander,* and *saurian.* In modern times a few examples of bones of men, found under circumstances arguing great antiquity, have been recorded. Upon strict examination it appears that in most cases these remains belong to a later epoch than the diluvial convulsions: the petrified bodies of the coast of Guadaloupe are enveloped in comparatively recent accretions; the human remains of the valley of the Elster, near Leipzig, appear to have been inhumed since the general dispersion of diluvium; the woman found in Paviland cave was of an early British era. The only cases remaining for further examination are some caves in the South of France, where the remains of Man and rude pottery are found mixed with a quantity of bones belonging to extinct species of animals of the mastozootic era; superficial deposits in Baden and in Austria, where remains of men with depressed skulls (as if occasioned by unnatural bandages) are found; and the remarkable notices by M. Boué of mingled human and animal remains in the breccia of Nice and Dalmatia.

In South France.

Without stopping to discuss the yet imperfect evidence concerning the antiquity of these remains in the breccia and superficial accumulations, we shall pass to the consideration of the caves in the South of France. From the examinations of Tournal, Christol, and Marcel de Serres, a considerable body of evidence has been collected concerning the caverns of Bize, (Aude,) Durfort, Pondres, Souvignargues, (Gard,) and from the similar state of conservation as well as mixture of the bones of men and animals in the caverns of Bize, M. Tournal decides positively that their age is the same. These animals are stag, chamois, roebuck, antelope, and bear, which hardly require to be considered of the mastozootic era. The same conclusion was drawn by M. Christol, from subsequent researches in the caverns of Gard, in which the animal remains were decidedly of the same era as the fossil elephant and rhinoceros. But the most instructive, probably, of all these discoveries, is that of the cavern of Miallet, near Anduze, (Gard,) completely investigated by M. Teissier. This grotto, situated on the banks of the Gardon, is opened in a dolomitic rock subordinate to the lias, on a steep slope, thirty metres above the valley. The lower layer of the interior of the grotto is dolomitic sand, irregularly overspread by a thin stalagmitic crust, and in places by an argillo-ferruginous mud, more than a metre thick, and adhering in several places to the roof and sides. In this bed were discovered in great abundance, and excellent preservation, bones and teeth of large bears, and with them a few bones of hyæna, ruminantia, and birds; under the stalagmite, and under a bed of loamy sand from two to four decimetres, a great number of human remains was found in various parts of the grotto. In the depth of the cavern they are unquestionably mixed with the bones of bears, which predominate; towards the entrance, on the contrary, human remains are most abundant, and appear of less antiquity. Upon the ossiferous loam, under a little projection of rock, was discovered a human skeleton nearly entire, near it a lamp and small figure in earthenware; further off bracelets of copper; in other situations coarse pottery, wrought bones, and edge tools of flint, indicative of ruder industry. The human skulls were depressed from above, apparently by artificial means, thus presenting a deceptive resemblance to the negro, though really belonging to the Caucasian race of men.

M. Teissier infers from these data that the accumulation of distinct periods can be traced in this cave:—1. The mastozootic or antediluvian era of the bears, with whose remains those of men are mixed, perhaps by subsequent natural or artificial means. 2. The era of rude civilization, (probably Celtic,) when the coarse pottery, flint tools, &c. were introduced, perhaps, to grace the sepulture of individuals. 3. The era of Roman Arts.

There is no necessity of hazarding a definitive conclusion on the antiquity for these human remains, because there is very great probability of gathering much additional information by the discovery of new caves under different circumstances. In the mean time we may remark that the principal arguments for the coeval existence of men, and extinct pachydermata and carnivora in the South of France, is the intimate mixture and equal conservation of the bones; and these arguments should not be slighted, for they would, probably, not have been resisted in any case of the mixture of quadrupedal remains. On the other hand, the known facts that many parts of the Mediterranean shores were anciently possessed by Troglodytic nations, and that the custom of burying in caves, as well as retiring to them for safety, was very general in these Countries, adds great force to the opinion of M. Desnoyers, that, in most cases, the human remains are of no greater antiquity than the early Celtic Ages, in which very similar works of Art were executed. (See Desnoyers, *Rapport à la Soc. Géol. de la France,* 1831.)

It is clear that ossiferous caves have received their contents, some at one period, and some at another, and that in others operations of the same kind, repeated at very different periods, have consigned to our investigation monuments of all the great zoological changes which have happened on the dry land since it first became tenanted by mammalia. The whole subject must yet receive a great accession of well-observed facts. One remark, concerning the excessive rarity or non-existence of human remains in diluvium, and in caves of the elephantoidal era, may be of considerable importance. Those parts of the Earth's surface to which traditions and, perhaps, general reasoning, seem to point as the first sites of the human race, the central regions of Asia, have been as yet little examined with reference to this question. It may be very possible yet to discover them there even in abundance, though in the high Northern regions men may not have existed till much later periods. It is a singular fact that the Quadrumana or monkey tribes which, so nearly approach to the bodily organization of man, are equally absent from the deposits of which we are speaking.

Upon the whole, the evidence yet obtained concerning *the Geological period* when the human race began to exist on the Globe, is very imperfect, and we may, perhaps, wait long for more full information. In the mean time, it may be stated as a general admission that Man did not exist on the Globe during the secondary, and, probably, not during the epoch of tertiary formations, and that sufficient evidence for his coexistence in Northern climes with the mammoths and hippopotami is yet wanting; but as the races of oxen, horses, camels, &c. had then begun to exist, it is a reasonable expectation that, eventually, this question will be decided in the affirmative.

We shall conclude our remarks on this interesting

Cause of diluvial action.

class of deposits by some attempt to assign the causes of the diluvial phenomena. Those who refer these effects to one universal flood sweeping over the whole Globe, must of necessity ascribe such a mighty catastrophe to some great astronomical cause, such as the appulse of a comet, or the displacement of the axis of the Earth, or appeal to a miracle. But as we cannot venture to assume that what we name diluvial phenomena are of universal extent, or were occasioned by a single convulsion, nor are entitled at our pleasure to disturb the harmony of the Solar system, nor to help our ignorance by invocation of miracles, these conjectural hypotheses must be passed by in silence. From what has been previously stated, we are entitled to look upon the diluvial epoch as a short period of violent tumult in the ocean, like many which have happened before; perhaps more extensive, but certainly similar. Why, then, should we not refer it to the same causes? As the elevation of the beds of the sea after the grauwacke period, after the carboniferous period, after the cretaceous period, produced large and violent floods, and caused the formation of extensive conglomerates, so the elevation of the Alps may have caused the diluvium which has rolled from them, and the elevation of the Scandinavian chains may have caused the transport of their granites, sienites, and limestones across the Baltic, and along the plains of Germany. That the Alps have been elevated from deep sea is the universal conclusion of observers; that the whole chain has been raised at a comparatively recent period is certain; and there appears every reason to believe that the dispersion of the boulders was consequent upon the elevation of those parts of the Alps from which respectively they were detached.

We cannot apply this mode of reasoning to the Cumbrian mountains in England, for these appear to have been elevated above the sea at a far earlier epoch than that now under discussion. In this case, then, the effect must be ascribed to a *cause acting from a distance*, which would agree with the magnitude of the phenomena observed, and lead to the notion of some very general convulsion preceding the diluvial movements. Upon the whole, we will venture to conclude that the diluvial currents were occasioned by convulsive movements of parts of the solid fabric of the earth, of sufficient force to throw the waters of the sea over distant regions of dry and elevated land.

Table of Organic Remains in Caverns and Superficial Deposits subsequent to the Tertiary Period.

N. B. Extinct genera are marked with an asterisk. Caverns marked with (*c.*) Breccia with (*b.*)

Name.	In Caverns and Breccia of all Ages.	In Diluvial and Earlier Accumulations.
Remains of men	*c.* Gailenreuth, Zahnloch, Paviland, Bize, Durfort, Pondres, Souvignargues, Sicily	Kostritz, Rhine Valley, Austria, &c.
	b. Nice, Dalmatia.	
Vespertilio	*c.* Franconia, France	Köstritz.
	b. Cagliari, Antibes.	
Sorex	*c.* Avison.	
	b. Sardinia, Dalmatia	Ditto.
Talpa	*c.* Avison	Ditto.
Ursus spelæus, Blum.	*c.* Germany, France, England	Chatillon.
	b. Krain, near Krembs, Munster	
arctoideus, Blum.	*c.* Franconia, Bize, Sallèles, Lunel Vieil.	
cultridens, Cuv.	*c.* Sundwich, Kent's Hole	Val' d'Arno, Puy de Dôme.
other species	*c.* Franconia, Sundwich, Fouzan, Sallèles.	
	b. Perpignan	Puy de Dôme
Nasua, Cuv.	*b.* Nice.	
Meles vulgaris	*b.* Lunel Vieil, Sallèles.	
Gulo spelæus	*c.* Gailenreuth, Sundwich.	
Viverra, Clift	*c.* and *b.* Australia.	
Canis spelæus, (Wolf.)	*c.* Franconia, Bize, Sallèles, Kirkdale	Yorkshire.
	b. Sardinia.	
familiaris	*c.* Lunel Vieil.	
other species	*c.* Franconia, Bize, Sallèles	Val' d'Arno, Avaray.
Vulpes vulgaris ?	*b.* Sardinia ; *c.* Kirkdale	Perrierburg.
Hyæna spelæa, Goldf.	*c.* Kirkdale, Plymouth, Swansea, Paviland, Muggendorf, Harz, Fouvent, Sundwich, Lunel Vieil, Pondres, Kent's Hole, &c.	Köstritz, Canstadt, Eichstadt, Val' d'Arno, Herzburg, Abbeville, Lawford.
other species, Goldf.	*c.* Franconia, Sundwich, Lunel Vieil	Puy de Dôme, Velay.
Felis spelæa, Goldf.	*c.* Kirkdale, Plymouth, Gailenreuth, Baumann's Hohle, Sundwich, Lunel Vieil	Köstritz, Val' d'Arno, Bielbecks in Yorkshire.
antiqua, Cuv.	*c.* Gailenreuth ; *b.* Nice.	
other species		Upper Italy, Puy de Dôme.
Mustela (polecat)	*c.* Lunel Vieil, Gailenreuth.	
(weasel)	*c.* Kirkdale.	
Lutra antiqua, M. de S.	*c.* Lunel Vieil.	
other species ?		Puy de Dôme.
Dasyurus, Hypsiprymnus Halmaturus Phascolomys, kanguroo and wombat	*c.* Australia. (Clift.)	
Castor	*c.* Lunel Vieil	Val' d' Arno, Puy de Dôme.
*Trogontherium Cuvierii, (Fisch.)		Taganrok, near the Sea of Azof.
Werneri, Cuv.		Jaroslav.
*Osteopora platycephala (Harlan)		Near the Delaware.
Mus	*c.* Kirkdale, Sallèles *b.* Gibraltar, Sardinia	Lawford
Arvicola	*c.* Kirkdale, Gailenreuth, Sundwich, Gibraltar, Nice, Cette, Corsica, Sardinia.	
Hystrix		Val' d' Arno.

Name.	In Caverns and Breccia of all Ages.	In Diluvial and Earlier Accumulation
Lepus diluvianus and others.	*c.* Kirkdale, Franconia, Sundwich *b.* Cette, Corsica, Nice	Puy de Dôme.
Lagomys corsicanus, Brurdet	*d.* Sardinia, Gibraltar, Cette, Nice.	
Chloromys		Ditto.
*Megatherium Cuvieri		North and South America.
*Megalonyx Jeffersoni		Ditto.
Dasypus, Bravard		Puy de Dóme.
Elephas primigenius, Blum.	*c.* Kirkdale, Warksworth, Mendip, Swansea, Muggendorf, Fouvent	Very generally in Europe, Asia, and North America.
meridionalis, Nesti		Upper Italy, Puy de Dôme.
priscus, Gold., resembling the African elephant		Yorkshire, Rhine Valley, Wittenberg, Russia.
several other species, according to Fischer		Russia, Podolia.
*Mastodon maximus, Cuv.		Very general in North America, Norfolk. (Smith.)
angustidens, Cuv.		
andium, Cuv.		Andes. (Humboldt.)
Humboldtii, Cuv.		Chili.
elephantoides, Clift.		Irawadi in the Birman Empire.
latidens, Clift		Ditto.
arvernensis, C. and J.		Puy de Dôme.
Hippopotamus major, Cuv.		In England very generally, Upper Italy, Puy de Dôme.
undetermined	*c.* Palermo, Australia	Irawadi.
Rhinoceros tichorhinus Cuv.	*c.* Kirkdale, Warksworth, Plymouth, Swansea, Harz, Sundwich, Fouvent *b.* Nice.	Siberia, England, Germany, France, Val' d'Arno.
leptorhinus	*c.* Lunel Vieil	Cussac.
minutus, Cuv.	*c.* Lunel Vieil, Pondres, Souvignargues.	
elatus, C. and J.		Puy de Dôme.
undetermined		St. Privat d'Allier.
*Elasmotherium Fischeri		Siberia.
Equus, perhaps more than one species	*c.* Bize, Sallèles Argou, Pondres, Lunel Vieil, Fouvent, Kirkdale, Mendip, Clifton, Plymouth, Swansea *b.* Nice, Antibes, Gibraltar, Dalmatia, Arragon	Köstritz, Brunswick, Canstadt, Val' d'Arno, Oxford, Essex, Yorkshire, (frequent,) Lawford, &c.
Sus	*c.* Mendip, Bize, Franconia	Oxford, Val' d'Arno.
other species	*c.* Sundwich	Puy de Dôme.
*Chœropotamus	*b.* Villefranche-Lauraguais	Irawadi.
*Mericotherium Sibericum		Siberia.
Cervus megaceros, Hart.	*c.* Kent's Hole	Very general in lacustrine deposits, probably less ancient than the diluvial deposits, England, France, Ireland.
tarandus priscus	Brengue	Europe.
tarandus		Köstritz.
dama giganteus		Abbeville.
polignacus		Cussac,
elaphus	In English caverns generally	Frequent in England.
Reboullii, Christol.	*c.* Bize, Sallèles.	
several others	*c.* Ditto, ditto *b.* Gibraltar, Cette, Nice, Antibes, Pisa.	Cussac, Puy de Dôme.
Antilope Christollii, M. de S.	*c.* Bize, Sallèles.	
other species	*b.* Nice, Arragon	Irawadi, Köstritz.
Ovis	*b.* Villefranche-Lauraguais.	
Bos primigenius, Bojanus	*c.* Sallèles, Bize, Lunel Vieil, Argou, Pondres, Souvignargues.	
priscus, Boj.	*c.* Bize, Souvignargues, Lunel Vieil, Pondres, Argou, Sallèles	Siberia, North America? Yorkshire, and various parts of Europe.
bombifrons, Harl.		Bigbone Lick, &c.
trochocerus, Von Meyer.		Upper Italy.
Pallasii, Dekay		Siberia, New Madrid.
Velaunus		Cussac.
undetermined	Kirkdale, Mendip, Plymouth, &c.	In various parts of England.

We have not ventured to admit into the preceding list, the numerous remains found in the irony sands of Eppelsheim, which are stated to be related to the tertiary limestones of that vicinity, in which also (see Meyer's *Palæologica*) bones of rhinoceros, &c. occur. These remains consist of species of gulo, felis, (not those of the caverns,) several small rodentia, cricetus vulgaris? moschus antiquus, 5 species of cervus, (not those of the diluvium,) rhinoceros Schleiermacheri, (Kaup,) mastodon angustidens, m. arvernensis, 3 species of equus, tapirus priscus, lophiodon Goldfussii, sus antiquus, s. palæocherus, dinotherium giganteum, d. bavaricum, manis gigantea

It may be remarked that in the valley of Rhine, and in some other parts of the Continent of Europe, where local tertiary seas have left agitated deposits along their shores, and in the line of their currents, it requires extreme caution to apply with propriety the term diluvial. By an appeal to the organic exuviæ, where these are sufficiently plentiful, it may often be possible to resolve the doubt, especially where remains of the pachydermata are numerous. Thus elephants, hippopotami, rhinoceros tichorhinus, and certain bovine and cervine remains on the one hand, and, on the other palæotheria, lophiodonta, &c. offer strong contrasts. But this test cannot always be applied, and it then becomes difficult to rely on the minute distinctions which probably almost always exist between the tertiary and diluvial species of the same genus. In this research much yet remains to be effected. Cases like those of Eppelsheim and Georgesgemund become in this point of view exceedingly important; for, by a comparison of many such instances, the series of zoological changes on the land, between the beginning of the tertiary and the end of the diluvial periods, may perhaps be eventually determined. At present we can only perceive that in general the palæotherian inhabitants of Europe had mostly ceased to exist in these limited districts before the elephantoidal races had spread themselves so widely over the Northern zones; and can clearly show that the proportion of species belonging to extinct genera in the undoubted tertiary deposits, was at least half, while in the undoubted diluvial deposits and caverns of the same date, it was about one-fifth. The remarkable extinct genus mastodon is common to the tertiary and diluvial periods, and there seems good reason to think that in some of the localities in North America, remains of these animals lie in postdiluvial lakes, like those which contain in Ireland and Yorkshire the bones of the cervus megaceros. Some remarks bearing on the general question of the determination of the Geological epochs of marine and littoral deposits, by comparison of their quadrupedal remains, will be found under the head of the tertiary strata.

Deposits of the Modern Era.—Modern Causes in Action.

Relation of terraqueous agencies in ancient and modern eras.

Having now concluded our descriptions of the strata and aqueous products recognised in the crust of the Globe, and also traced the effects of subsequent extraordinary inundations upon the surface, arising from local changes of level or general internal convulsions, it remains to be seen whether the causes now in action in the modern economy of Nature are of the same *kind* as those which were formerly concerned in producing the arrangements and disarrangements observed in the crust of the Globe.

This is the true cardinal point of theory. According as the one or the other conclusion on this point be adopted, we may attempt to explain the ancient phenomena by modern laws of Nature, and thus connect the present and the past, the extinct and the existing history of our Planet into one system of progressive change, according to the school of Hutton, Playfair, and Lyell; or suppose that in the chaotic infancy of our Planet, laws peculiar to that period prevailed, and properties of matter were unfolded then which never show themselves at present; and that the ancient rocks and organic bodies belong to a wholly distinct set of causes, were the produce of a peculiar creative impulse, no longer permitted to operate on the finished and man-inhabited Planet. The Wernerian cosmogony bears very much this aspect.

But though, put this in direct opposition, the rival hypotheses appear to have no point of union, we find, in fact, that between the opinion of Hutton, who considers Creative Nature to be perpetually in progress,—the same to-day, yesterday, and for ever—and the dogma of Werner, that the World was made by a certain settled sequence of events, to which nothing similar now hap pens, every variety of theory is adopted and defended We may, however, with rigid accuracy and much convenience, rank them in three classes.

1. The favourers of Hutton's and Lyell's views, who maintain that the causes now in action to change the level and alter the relations of the masses of matter near the crust of our Globe, are those which have ever been in action, identical in kind, and equal in degree, in all times past, and which may be expected to continue the same, in kind and degree, through the future.

Views of the English School on this subject.

2. The general School of English Geologists, who have always maintained, and laboured to prove, that the causes operating on the surface and in the interior of the Earth have remained through all times past unchanged in kind, and are still operating with the same tendencies as they always did, but on smaller areas, and with less effect. This view of the subject has a double aspect. English Geologists have generally believed that as volcanoes were supposed to become languid through want of fuel, the *circumstances* under which the modern operations of water and fire are manifested in the general economy of Nature, approach more nearly to a state of equilibrium or saturation, and therefore afford no opportunity for the same extraordinary display of energy as in ancient times; but since the relative periods of the great convulsions which have elevated chains of mountains, and given new boundaries to the ocean have been investigated upon sound principles, the mind has become gradually familiarized to another notion, and habituated to contemplate long periods of ordinary and regular action of natural causes, interrupted by transient local or general convulsions. According to this modification of the hypothesis, the present is a period of ordinary and regular action, succeeding upon an epoch of violent disturbance.

3. The old notion of despairing speculators in cosmogony, who found it easier to cut the Gordian knot, by flatly denying the analogy of modern and ancient operations, and either referring the whole beautiful order of the ancient works of Nature which they could not comprehend, to a momentary fiat of Deity, or to the rude and prolonged confusion of elements in chaos.

This is the only notice we shall take of that mere dream of indolence and deficient observation; for we have already proved that the stratified rocks are certainly analogous in all points to the products of modern waters, and that the unstratified rocks clearly prove their special origin from fire.

As in our accounts of the construction of the Earth' crust we have resolved to separate the results of the an cient operations of fire and water, so in our views of the modern effects of these agents, the same plan will be followed; and, without stopping at every point to settle the precise amount of inference due to every datum, we shall present a connected view of the continual effects o the atmosphere, rains, springs, rivers, and the sea, on the surface of the Globe, before proceeding to the changes occasioned by more occasional eruptions of igneous agents from below, volcanoes and earthquakes, and other connected phenomena. Some general inferences, suited to the present state of the Science, may occasionally be ventured, and perhaps many years must pass before any one acquainted with the peculiar temptations to insecure hypothesis which sciences of observation hold out, will venture to dignify his imperfect generalizations with the delusive title of a Theory of the Earth.

Wasting Effects of the Atmosphere.

The gradual wasting of the surface of the higher parts of the Earth is an important element in Geological theory, and it is scarcely to be supposed that any Geologist can be so entirely engrossed with the contemplation of the ancient operations of water in producing the stratified crust of our Planet, as to neglect the consideration of the analogous effects which are in progress at the present time. The following examples of the varied effects of atmospheric influences, in modifying the surface of the erections of man and the works of Nature, are derived from the writer's own observations, and it is to be supposed that they form but a small part of the current information on the subject.

The wasting effects of the atmosphere are those initial or preparatory processes by which earthy materials are provided for rivers and the sea to transport and deposit in new situations.

These processes, as far as they depend on the atmosphere, are chemical when the atomic composition and the properties of the parts are changed, mechanical when their state of aggregation is altered; and this may happen by general humidity, variations of moisture, variations of temperature, or precipitations of rain.

It is not, however, always possible to distinguish accurately the effects of these several causes. Many natural agencies are often concerned in one operation, and the general result is the sum or the difference of their effects. The chemical effects of the atmosphere are evident in buildings and on the surface of certain rocks. The same process which slowly reconverts the mortar of walls into carbonate of lime, frequently causes the pulverization and bursting of the bricks, in consequence of the expansion of the small masses of lime which they contain.

The surface of bricks is often covered with a saline efflorescence, which is generally nitrate of lime, but sometimes muriate of soda. The surface of the yellow limestone near Doncaster is sometimes covered with a nitrous efflorescence, and so is the calcareo-magnesian mortar made from it.

Waste of Felspathic rocks.

The exterior of most uncrystalline rocks and buildings seems to be slowly eaten away by the moisture and carbonic acid of the air; but the influence of this destructive agent is most remarkable among the felspathic rocks, whether like granite they are originally crystalline, or like millstone grit composed of fragmented masses. The felspathic portion of the hypersthene rocks of Carrock Fell is so wasted that the crystals of hypersthene and magnetic iron are projected from the surface considerably. Some greenstone dykes are thus entirely decomposed to great depths from the surface, and whole rocks of granite, secretly rotten, wait only for an earthquake, or a water-spout, to be entirely reduced to fragments. Those who have seen the crumbled granite of Muncaster Fell, or Castle Abhol in Arran, surrounded by heaps of its disintegrated ingredients, must have been struck by the importance of this phenomenon in reasonings concerning the origin of many stratified rocks.

Both carbonic acid and oxygen act very decidedly upon the metallic, and particularly the ferruginous ingredients of rocks, and thus swell and burst them to pieces. Sometimes, however, this very cause seems to harden and bind together the rock, and to render it more durable, and in general, there is no certain test of the durability of any stone but experience under the same circumstances. The Bath stone, so permanent amongst its native hills, perishes in the salt air of Norfolk, and few calcareous freestones of any kind will long resist the carbonaceous atmosphere of London.

Preserving power of the ground.

It is worthy of remark, that sculptured stones buried under ground are perfectly and even wonderfully preserved, while their fellows left exposed to the sky have been almost crumbled to dust. A fine example of this was noticed in the course of the excavations for the Yorkshire Museum, by which the statues which once stood between the arches of the nave of St. Mary's Abbey were discovered, some with blue others with red drapery, one with gilded hair, all retaining the most delicate chisel marks. A few yards from them, at the West end of the Church which they once adorned, the atmospheric influences have nearly obliterated a beautifully sculptured wreath of leaves round the doorway, so that Antiquaries have doubted whether they were meant to represent the vine or the ivy.

Waste from humidity,

Frequently, in looking at buildings composed of porous materials, like the Portland stone, or a grit freestone, we observe the parts which are overhung by a ledge, and thus kept in a state of continual shade and dampness, to be more rapidly consumed than the projections; but the parts which hasten soonest to decay are those near the ground. The same rules are exemplified in many remarkable rocks, as for instance in the quartzose conglomerates of the old red sandstone of Monmouthshire, and the millstone grit of Brimham Crags in Yorkshire. The "Buckstone" near Monmouth is a huge rock inversely conical, expanded above into a large area, but contracted below by continual waste to a narrow base of attachment. This process, a little further continued, might convert the buckstone, as probably some of the stones of Brimham have been converted, into a "rocking stone."

from changes of heat and moisture;

In Northern zones the variations of heat and moisture are greatest on the South and West fronts of buildings, and in consequence those fronts to our Cathedrals decay most rapidly. This is remarkably the case with the grand Cathedral of York built of magnesian limestone, which is in many places quite consumed on these fronts, but comparatively uninjured on the Northern face.

The weathering of the surfaces of buildings by the fluctuations of heat and moisture is partly dependent on the structure and composition of the stone. The flagstone of Yorkshire is in many houses at Bradford gradually decayed grain by grain, so that the surfaces of the stone, continually renewed, and never permitting the growth of lichens, appear always neat and clean. The magnesian limestone of the same County, often traversed by veins of calcareous spar, presents frequently a cellular or honeycomb appearance, in consequence of the projection of these veins above the excavated limestone; but the coarse shelly beds of the Northamptonshire oolites, and the irregularly laminated millstone grit, are decomposed in lines corresponding to the inequalities in the composition of the stone.

In these cases the stone appears to undergo gradual and continual waste; but sometimes the whole surface exfoliates. Basalt very frequently suffers this kind of waste, granite not seldom, and it has been supposed in these instances, that the atmospheric action merely discloses the latent concretionary structure of the rocks.

The following examples require a different explanation. The bridge over the Wear beneath the Western towers of Durham Cathedral built (about 40 years ago?) of a sandstone associated with coal, is ornamented with a balustrade, and the little pillars are worked with various swellings and mouldings. In crossing this bridge many years since, the writer struck one of the balusters with his hammer, and being much surprised with the hollow noise which ensued, stopped to ascertain the cause. It was found, in many instances, that a thin, external coat of stone parallel to the mouldings was entirely separated from the internal nucleus, and ready to scale off upon the slightest blow. The Western front of the ancient and beautiful little Church of Skelton, near York, built of magnesian limestone, shows the same kind of decay in a direction across the bed of the stone. The Yorkshire flagstone is occasionally used, to make curb stones of two feet in height, the laminæ being placed vertically, and the block worked above to a semi-ellipsoidal figure. Even these laminated stones frequently exfoliate parallel to the tooled surface. The ramparts of Zurich are built of sandstone, belonging to the tertiary system, (molasse,) and the stones are cut with a boss along the middle and a depressed border. Desquamation happens parallel to the artificial surface.

Since, in these various instances, desquamations are found to occur parallel to the surface, without reference to the internal lamination of the stone, the mere circumstance of exfoliation seems insufficient to demonstrate the originally concretionary structure of basalt and granite. It is, nevertheless, very probable on other grounds, that basaltic pillars, if permitted to assume their natural shapes, without pressing one against another, would resemble a number of superimposed spheroids.

All the cases of desquamation seem to arise from an alteration of the degree of coherence of the stone, whereby the external crust is made to expand and contract differently from the internal parts, and, in consequence, is soon separated from them. The surface of stones long exposed to the weather is frequently much indurated, while the inner parts remain soft. (This is the case in the outer circle of Stonehenge. Mr. W. Smith.)

from frost.

Frost is likewise an important agent in reducing to smaller masses the materials of the Earth. Some stone, if brought to the surface in Winter full of its "quarry water," will break in pieces directly. Advantage is taken of this circumstance by the slate-workers of Stonesfield and Collyweston, who quarry their stone in the Winter, taking care to shield it from the Sun and the wind till the frost has acted upon it, with the aid of affused water, if necessary, which, by disclosing the natural fissility of the stone, permit the blocks to be cleft into thin, sound, roofing slate. Landslips in mountainous regions are, probably, much accelerated by the power of frosts. In ascending the Righi from Weggis, on the Lake of Lucern, we are much struck by the extraordinary length and continuity of the joints of the nägelflue. It is from these natural partings that the landslips fall, when repeated rains, snows, and frosts have worn or burst them open, and the water passing down them undermines the foundation of the cliff. Thus huge blocks, liberated from their attachments, roll down the steep descent, or half the summit of a mountain slides upon its argillaceous bed. Vast portions have thus slipped from the Righi towards the Isthmus which divides the Lakes of Zug and Lucern, and others are preparing to follow. The fissure is already opened parallel to the edge of the precipice, and pervious below, so that a stone thrown in at the top, is said to fly bounding out at the base.

Effects of rain

We come now to the effects of rain, and without dwelling on the general degradation of the softer surfaces of the Earth caused by this agent, we shall proceed to show, that within the historic era hard and durable stones have been greatly furrowed by the rain, and that in more ancient periods, the precipitations from above have carved themselves channels of various kinds, and sometimes occasioned real though miniature valleys of great length and continuity.

on monumental stones, &c.;

Many Druidical monuments in the North of England are constructed of coarse millstone grit, a rock admirably suited for yielding those enormous blocks preferred by the ancient Architects. Three huge Druidical stones, now standing near Boroughbridge, called the "*Devil's Arrows*," present us with a most instructive lesson on the ultimate fate of all human erections exposed to the ravages of time.

The rain, beating for 2000 years upon these venerable pillars, has cleft their tops, and ploughed deep furrows down their sides. The grooves are deepest at the top, and become wider and less distinct towards the bottom; they cross indifferently the false-bedded layers of pebbles, and go directly downwards. One of the stones leans remarkably and threatens to fall, but an examination of the furrows shows the inclination to be of most ancient date, for they descend much further down the pillar on the upper inclined face than on the under.

Similar effects of rains are visible to a greater extent on the bold crags, like Almias cliff and Brimham rocks, which crown the summits of so many hills of North-Western Yorkshire, from some of which the Devil's Arrows were obtained.

In the valleys of Swisserland (Sarnen) blocks of limestone, which have fallen from the mountain sides, have been furrowed in the same way since their descent.

on rocky cliffs and floors.

The carboniferous limestone of England has been little employed in building, except partially in old castles, where it seems durable, and they who know the magnificent ranges of scars which begird the hills of Derbyshire and Westmoreland, will acknowledge that few rocks seem more likely to endure the rage of the elements. But yet close inspection of these giant cliffs will prove that time has been busy there. The dry and bleached aspect, and the smoothed angles, show plainly the wasted surface. Those who have stood on Doward Hill, near Monmouth, to contemplate the rain-furrowed white limestone there, will not need another example. In the North of England analogous and more remarkable instances present themselves in the wide limestone base of Ingleborough, and in Hutton roof crags near Kirby Lonsdale.

The vast limestone floor which supports the cone of Ingleborough is marked in all directions by natural fissures, and divided into compartments like a map.

If one of these compartments be examined in the Western part of the mountain, its surface will be found scooped into little hollows which unite into a common channel, and terminate by indenting the edges and furrowing the sides of the fissure. They are, in truth, valleys in miniature, separately produced by the drainage, so to speak, of the several blocks.

The mere decomposing effect of the atmosphere produced on the edges of the stones a different effect, by wearing away the softer laminæ, but the smooth surface of the miniature valleys, their regular descent, winding course, and union into a common channel, show that they were fashioned by the repeated operation of descending rain.

This scar is nearly level, but in Hutton roof crags we have an opportunity of tracing the rain channels over an immense surface of bare limestone rocks lying nearly level on the hill top, but sloping rapidly down the sides to the East and South. On the level top of the hill the stones are variously worn in hollows and grooves irregularly united and running in different directions according to little variations of the ground; but on the steep East and South slopes the channels are extended into long furrows, which, uniting at acute angles, enlarge, widen, and descend the hill side, in lines following exactly the declination of the rocks, and stopped only by the few and distant fissures beyond which other systems of concurrent grooves begin.

Rain channels like miniature valleys.

It is impossible by drawings, or descriptions, to convey such an idea of the appearances of the Hutton roof crags, as to awaken in others the deep impressions which are fixed for ever in the mind of the observer. The astonishing resemblance which these little rain channels present to the great system of valleys which undulate the stratified rocks, seizes upon the imagination, and we re-examine all our notions of the origin of these great undulations. The fissures in the limestone rocks which stop and swallow up the gathered streams, are analogous to those longitudinal valleys beneath the escarpments of the oolites, and the chalk by which the rivers are turned at right angles to their earlier course, while the lower edge of the fissure corresponds to the escarpment itself, with its new system of denudations.

To see these rain and time-ploughed furrows winding in uncertain directions over the horizontal limestones on the hill top, like a slow river in a level plain, but running a straight downward course on the slopes, like a stream descending from its parent mountains, is enough to impress on every beholder a secure conviction that the excavation of valleys must be explained upon similar principles; that, as the feeble currents of descending rain, aided by long time, have been sufficient to plough their little courses, so the greater action of existing streams has been sufficient to work out their actual channels, though the excavation of the broad valleys in which they run, may have been accomplished by more violent and voluminous waters, flowing in directions predetermined by ancient subterranean movements.

Effects of inundations.

It is probable that the slow but incessant action of rain, beating perpetually on the hard and the soft surface of the Earth, and removing grain by grain the materials loosened by the expansive agency of frost, moisture, and chemical changes, may be, in a given long series of years, more important in its effects than the violent water-spout, or the ravaging inundation of a bursting lake. Yet the effects of water-spouts are tremendous in Countries composed of easily destructible or unequally indurated materials. A water-spout which fell on the mass above Kettlewell in Yorkshire, committed the most terrible ravages in the narrow valley of the Wharfe, near Kettlewell and Starbottom. On the sides of the mountains in Cumberland, traces of these visitations seem utterly ineffaceable; and the memory of the sudden bursting of the Peat Bog above Keighley, will long be preserved in the valley of the Aire. The floods which rushed simultaneously from the Cairn Gorum and other mountains, in August 1829, over 5000 square miles of Aberdeenshire and other Counties, were of prodigious fury, removing hundreds of tons of large stones, whole acres of woodland, and almost hills of earth. The desolating effects of the bursting of the ice-dam which had formed the temporary Lake of Bagnes, are matters of history. The moving mass of water, mud, and monstrous rocks, which swept with violence down the valley of the Dranse, carried away forests, houses, bridges, cattle, and men. In six hours and a half it passed through an unequal and irregular course of forty-five miles, till its waves were lost in the Lake of Geneva.

Glaciers are likewise to be enumerated among the powerful agents by which the higher lands are wasted, and materials provided for the raising of the lower. As the Summer heat melts every year the lower portions of these long winding rivers of ice, and the heated ground thaws, and the gathering water dissolves their foundation, the whole mighty mass of snowy ice slides downwards on its failing bed, ploughs up the stones, breaks up the rocks, and adding their spoils to the accumulations of the avalanches, throws to the sides huge banks of rubbish, provincially called *moraine*. The foot of the glacier is thus surrounded by an immense hill of loose materials which gradually find their way into the stream that issues beneath.

Descending Streams and Rivers.

The wasting effects of the atmosphere, noticed in the preceding section, are sensible in all regions, and therefore in every Country some materials are provided for the streams to transport. But the proportion of matter thus prepared in mountainous Countries is so vastly greater than elsewhere, that in general the less conspicuous effects of the same causes in lower regions are overlooked. The common notion respecting the action of alpine streams appears to be, that *these* are the principal agents of destruction upon the faces of the mountains, and it is to them that the actual waste of the surface is attributed. But though these streams are indeed active agents of excavation, their principal influence is of quite another kind, and it is chiefly by the *disposition* of the materials brought into them by rains, avalanches, and water-spouts, that they effect such important changes.

Erosive or excavating action of streams.

In considering the action of streams and rivers, we must distinguish between their powers of eroding or *excavating*, and of *transporting* solid matter.

The former is occupied on the channel and floodway, and its effects have relation to the *consolidation* of the matter traversed, and to the rapidity and volume of the moving water. About their sources, and for a long part of their early course, streams deepen continually their channels, and wear away their barriers of rock: but in their broad expansions near the sea, this power of excavation wholly ceases, as a general law, and is only evinced in particular cases, as when great bands are cut off or banks are undermined.

We have abundance of examples in all our mountain regions of the actual excavation of their channels by the rivulets and rivers. In the district of Aldstone Moor, the South Tyne runs to the North from the side of Crossfull, for some miles along a slope of shale, over the Tyne bottom limestone. In this shale, which is itself excavated into a broad valley, the river has evidently cut its own narrow yet sufficient channel; and no contrast can be more striking than that here afforded by the mighty valley of Tynedale, 1500 or 2000 feet below its bordering mountains, and the little channel holding the waters of the River Tyne. Every river in this manner works out its own channel in elevated regions, and in lower ground the soft clays and sands yield a passage to the feebler currents. In the level regions, along the rivers of Yorkshire and Lincolnshire, the channels have been many times changed, even by those sluggish streams, and still more in the deltas of the Rhine, the Nile, and the Mississippi; and among the Alps, this fluctuation of the river-courses is excessively irregular. No doubt, then, can remain of the fact that rivers and running waters excavate and alter their channels.

Mr. Lyell has given a remarkable case of the *recent* excavation in a bed of modern lava of a channel from 50 to several hundred feet wide, and 40 to 50 feet deep, by the River Simeto, flowing from Etna. Mr. Scrope has also shown similar phenomena to have happened in the volcanic region of Auvergne. In these cases the action of the river has probably been excited by the flowing of a current of lava across its course, so as to dam up the waters, and give them something of the force of a cataract.

Waterfalls, &c.

The waterfalls and cataracts upon the line of a stream afford some curious points of study. It is especially in these cases that the increase of excavating power, derived by a river from the solid matter which it transports, is most sensible.

A cataract is formed upon the River Eden, in Westmoreland, near Kirkby Stephen, by some remarkable beds of calcareous red sandstone conglomerate, and the pebbles which the river brings down, here contribute with the whirlings of the water to excavate many deep perpendicular pits, similar on a small scale to swallow holes on the mountain limestone ranges, or those romantic cavities on the Caldew in Cumberland. Below many waterfalls in Wales and Scotland, the same effect is produced.

But the most characteristic effect of a cascade, is that ceaseless undermining of its base and sides, and consequent rupture of the spout or edge of the fall, which causes by slow degrees the cascade to retire further and further up the mountain side, and produces those awful and still deepening portals of impending rocks, which so much aggrandize the sublimity of a noble *waterforce*.

This effect may be excellently observed in the carboniferous limestone district of the North of England, where so many beautiful streams leap from the beds of limestone over perishing shales and sandstones, and rising in foam sap and undermine the base of a large semicircular cliff, till at length the solid limestone crown gives way, and the insatiable river renews its destroying attacks. The same thing is seen in many of the Swiss waterfalls, particularly in the manifold falls of the Giessbach.

Mr. Lyell very ingeniously applies the acknowledged fact of the recession of the Falls of Niagara, which appear to have been pushed back several miles, at the rate of 40 or 50 yards in 50 years, to the possible discharge hereafter, through the St. Lawrence, of the waters of Lake Erie. Such a discharge would, of course, occasion a local *deluge*; but the lake is so rapidly filled up by sediment, that it is a question whether it will not become dry ground, before the falls of Niagara shall have been pushed back so far as to be capable of emptying it. The fall of the Rhine at Schaffhausen is a grand exhibition of the erosive power of water, particularly the wearing of the base of the two island pinnacles of limestone, which now stand proudly in the midst of the currents, but will eventually be hurled down the thundering cataracts.

Transporting power of streams.

In considering now *the transporting action of streams*, we may distinguish between such as flow through valleys of uniform declivity without lakes, and such as pass through broad receptacles of water, before arriving at the sea. As examples of the former, we may take many rivers of England; for the latter case, several rivers of England, Wales, and Scotland might be named, but much grander phenomena of the kind are witnessed among the streams which flow down from the snow-crested Alps.

Rivers without lakes.

A certain velocity of current is requisite for the transport of every kind of earthy matter, the finer the matter the less force will move it along. Hence in the lower parts of rivers, where their course relents, as they approach the sea, though they can no longer, as in their youthful energy, remove rocks and transport loads of sediment, their waters are muddy, and their channels and sides receive continual augmentation. Such a river as the Yorkshire Ouse is very instructive. As its branches descend from Shunnor Fell, Cam Fell, and Whernside, they transport daily and hourly from those elevated sites the materials accumulated by atmospheric changes and mechanical attrition, the soil, the stones, the loosened rocks, grain by grain, and piece by piece, move onward with the current, and thus the whole mountain region, by a slow yet not imperceptible progress, is lowered in height, and its wasted spoils swept away for ever. But let us follow this process. Wherever the valley originally presented great inequalities, these are constantly diminishing by the upfilling of the hollows, and at length the originally rugged chasm is changed by *additions* and *upfillings* into the smooth, evenly declining hollow, which, because of that smoothness and uniform declination, is supposed by many to be entirely a valley of denudation. In this process, the lateral action of rains and inundations from the sides of the valley, is a very important auxiliary. Any one who contemplates the valleys of the Jura, near Schaffhausen, and sees them in many cases rugged on the sides, and evidently traced by nature in a fit of convulsion, must be struck by the smooth, even, equally declining *plane* of their bottom, which cuts the rude precipices of the sides, and clearly indicates a subsequent powerful modification of the original harshness of the chasm. Still more abundant is the deposit of sediment as the stream glides into lower ground. There, above its narrow channel, rise the broad meads which, with every fresh inundation, receive a new coat of sediment, and above these swell the real boundaries of the valley, often consisting of water-worn materials, gravel and sand, left there by ancient floods of greater power, flowing at a higher level. As we approach the sea, when the tidal currents meet the freshes, the suspension of motion permits a great part of what sediment still remains to discolour the water to drop on the bed of the river, and its alluvial banks. Thus the streams become choked, their channels sinuous, their beds elevated, and the banks which confine the river, heightened both by Nature and Art, look like the ramparts and terraces of a lofty military road rather than the boundaries of a river giving passage to the drainage of the neighbouring country.

The same process at the mouths of rivers pushes their channel and their banks outwards into a cape or headland, and contributes to extend the whole breadth of the bordering coast, so that by the waste of the uplands the low land is filled up, the river-channels are raised, the coast is extended into the sea, and the sea filled with shoals and sand-banks. Thus the mouths of the Po, the Rhine, the Nile, the Euphrates, the Ganges, and the

Mississippi, have formed for themselves those broad deltas which, within the Historic era, have transformed ancient ports into inland towns, and carried fertile pastures into the area of the sea.

The substances transported by the stream, and deposited along its sides, are of course such as the hills around its sources, and above its channel, furnish; and according to the nature of the country, the almost incessant accumulations of earthy matter which thus take place, may be varied by interposed layers of vegetable reliquiæ. In tropical and warm regions, and in uninclosed Countries, this must be the case to a far greater extent than an acquaintance with European rivers would lead us to expect. The mighty forests of America, untouched by human industry, must annually furnish to the great rivers which intersect them, an immense spoil of trees, which being easily supported by the current, will be carried even to the sea, and either deposited at the river mouth, or drifted away on the waves.

Arrangement of materials.

The arrangement of the materials brought down by the streams is in general regulated by a tendency to the production of a level surface, and thus the original inequalities of a valley are continually lessened. In a high region like the Alps, the rough streams leave in the higher level chiefly a collection of pebbles and sand, and they are left in much local confusion; but still the general effect is a uniformly declining plane, through which the capricious stream finds itself new channels, and thus continually shifts its deposits over the whole, broad, pebbly surface. Such effects may be well seen on the line of the Arve, as it hurries down from the glaciers of Savoy. On the contrary, in the lower and more level expansions of a valley, where the gentler waters transport only fine sediment and vegetable reliquiæ, these materials are arranged in most exact parallelism over a large extent of plane surface, and by counting the laminæ of deposition, some useful notion may be formed of the period occupied in the process. On the borders of streams which are periodically swollen by rain, as in the Tropical regions, or by the melting of snows, as in those which descend from high mountain countries, this mode of computation of the laminæ may even be trusted so far as to determine the number of years employed in producing a given depth of deposit; and even in districts where the rivers swell irregularly at uncertain intervals, there might be an *average rule* for the same purpose deduced. Nor would the accumulation of a short period of time, tried by this test, appear inconsiderable. In a single season, the rivers of Yorkshire, aided by the sea, deposit many inches of rich soil upon the level peat-moors which adjoin their estuary; and at Ferrybridge, at the point where the tide, formerly flowing up the river, neutralized the freshes of that river, many of the modern works of man, as oars of a boat, a coin of England, were found buried under the alluvial sediment, which contained petrified hazel-branches and nuts, bones of the stag, &c.

From what has been said of the action of rivers, it is evident that their effects upon the physical features of a country are more varied and interesting than has been generally perceived by those who have written on the much controverted question of the origin of valleys. The tendency of all descending streams of water is the same, to equalize the surface of the earth, to remove all its ridges and asperities, and to smooth all its gulfs and fissures.

The degree in which they respectively perform this depends *first* on the amount of atmospheric and local influences in wasting the surface of the higher ground, and bringing materials for the rivers to act upon. Hence the rapid waste of high Alpine tracts exposed to fluctuating heat and cold, to storms, avalanches, and glaciers. Hence the streams of sand and pebbles which rush from the gritstone hills of England, and, on the contrary, the almost unsullied purity of the springs which break from the carboniferous limestone.

The *second* circumstance which determines the modifying power of the river is its own volume and velocity, and these are principally dependent on the physical geography of the region. The datum of the volume of water flowing in any valley is principally useful for comparison with the *amount of effects*; the *kind of effect* produced is determined by the *velocity* of the current.

If we conceive that in its first fury a river may have power enough to sweep along even large blocks of stone, but that its velocity gradually diminishes, there will be a certain point, where these large blocks will be left by the enfeebled current, pebbles will roll further, coarse sand will travel beyond, and the finer sediment will be moved on till the languid waters permit their slow and equal deposition. This gradation of deposits is always observed in examining valleys of sufficient length and elevations. The deposits in the upper parts are tumultuous and confused, in the lower regions level and regular.

A *third* circumstance, of still more importance than the others, serves to regulate the action of the river. This is the *form and character* of the valley itself. However produced, there can be no question that the present aspect of almost every valley in the World, is smoother and more equalized than it was formerly, since we see evidently and take as a principle, that the characteristic effect of modern causes in action is to reduce continually the inequality which remains. We may, therefore, easily, for each valley, restore in imagination its ancient condition, remove the sediment from its expanded meadows, and leave, instead of level or gently sloping planes that wind smoothly round the hills, and ascend far up toward the sources of the stream, deep chasms between cliffs rent asunder by convulsion, and ridges of rock confusedly crossing the gulfs of the strata. That such has been the origin of many valleys is perfectly evident. That these may have been partly cleared, and others wholly occasioned by violent floods, sweeping over and denudating the land during its elevation from the sea, or by some violent catastrophe at a subsequent period, is also very probable, or rather may be considered as proved. But without entering on these questions, we may content ourselves with the *datum* that the fundamental features of valleys are not the result of the excavating action of their streams, but that valleys have been in part filled up by the accumulations brought by their own rivers, and that their present smoothness and uniformity is really the result of the modifying powers of the atmosphere, local influences and the river, exerted through long time upon a ruder channel, left by more violent and transitory agents.

Rivers with lakes.

Let us now see what peculiarities in the effects of rivers are occasioned by the circumstance of their traversing quiet lakes. Two things are here to be attended to. First, the lake causes, according to its extent, a more complete deposition of the sediment brought by the rivers than is occasioned by the most level dry area of a valley; secondly, the materials dropped in the lake are regulated by somewhat different laws from those which direct their accumulation on the common surface.

When a river charged with sediment expands into the waters of a lake, its motion, communicated to that large area in directions radiating from the place of entry, relents, and is almost lost, and the sediment which it brought is gradually and, at last, wholly deposited in the lake, whose transparency it disturbs, and the purified stream issues from the lower extremity without a single taint of its stormy origin, *unless it be the colour* of the mountain-peat, or some other substance held in chemical solution. Like the lake from which it escapes, or the ocean far from shore, it generally assumes the purest ethereal hue, its native tint of green or blue, but soon in its onward course it again becomes turbid with sediment. Every lake in Swisserland exhibits these pleasing effects upon the rivers, which commonly enter in turbid violence, and issue of a lovely transparent green, but the Rhone is pre-eminently blue. These lakes are filling and contracting at their upper ends with the sediment which they filter from the rivers, and the process, though historically slow, is monumentally impressive, since we perceive large tracts of level meadows cultivated, covered with trees, and adorned by ancient and modern towns, where formerly flowed the deep waters of the lake.

All this *new land* was formed from the spoils and waste of the upper Countries drained by the river, and it is an exact measure of the whole effect of the atmospheric and local influences in weathering the face of the hills, and of the rivers in transporting away the materials thus prepared for them *from the earliest period when the streams began to flow* down the actual valley.

Arrangement of materials. The second thing to be attended to in considering the effects of lakes on the line of rivers, is the arrangement of the materials which they receive. This is a subject in which Mr. Yates's observations (*Edinburgh Journal*, 1831) will be found useful. It is known to practical men that loose earth will remain at rest if it be placed at an angle, not exceeding 45° with the horizon, and when loose, earthy materials are poured from a height, they usually arrange themselves in a conical heap, whose sides make nearly this angle with the horizon. On the slopes of mountains liable to avalanches or rapid waste, the loose débris is usually found in a plane declining at about this angle. When streams falling over an edge, pour with their waters a quantity of earthy matter, the conical heap so produced is very much more obtuse than when the materials fall dry, and the larger the proportion of water that comes down, and the more forcibly it descends, the flatter is the slope of the cone. This will easily be understood upon the principle that by partial suspension in water each particle is influenced by the tendency of that fluid to become level.

It is easy to understand from this that the form in which coarse sediment will be deposited by rivers entering a lake, must be in a very obtuse cone radiating round the point of entrance. As the heap of sediment is advanced into the lake by continual additions, its outline remains circular, with a larger radius, and its section will be nearly level toward the land, but sloping more and more rapidly toward the interior of the lake. Were the particles to be arranged in obedience to the double forces of horizontal movement with the river, and of perpendicular descent from gravitation, the curve of the edge would be parabolic, and the surface left upon the sediment toward the land nearly level.

But the earthy matter being unable to support itself at more than a certain angle of elevation, the lower part of the curve will become less steep, and be reduced to a straight line. Mr. Yates's observations on the Swiss lakes led him to assign to the sediment left therein an outline of this kind.

It is obvious that in these cases the sloping layers nearest the entrance of the stream are of older date than those further advanced into the lake. It is an interesting subject of inquiry to learn whether, as is most probable, the particles of the sediment which differ in bulk and specific gravity, are arranged according to those qualities so as to constitute horizontal strata, of finer and coarser matter, &c.; and whether, this being the case, the sloping lines of deposition, &c. are visible or obliterated in the section. In this manner the upper ends of lakes are filled with the deposits from the rivers almost to the surface, and the dams of the lower ends of the lakes being worn away by the incessant action of the stream, these deposits become visible above the water, and constitute those smoothly declining, often moist surfaces, which usually confine within their indefinite border the shallow and weedy waters destined in their turn to retreat from the desiccated land. While this process proceeds near the shore with the coarser particles, it is obvious that the finer sediment will be carried further into the lake, and be spread more widely over its general bed.

These remarks apply only to deep lakes, whose waters rest tranquilly on their beds, and are only agitated at the surface. In shallow lakes, which are agitated to the bottom, the materials must necessarily be distributed in planes very nearly horizontal, in consequence of the impressions from the fluctuations of the surface. This is matter of daily observation.

Before we dismiss the subject of lakes, it will be proper to take notice of another process tending also to fill them with new deposits. Lacustrine Deposits. Many streams which enter lakes carry along, dissolved in their waters, a quantity of carbonate of lime, which may afterwards, by the loss of carbonic acid from the water, fall in calcareous sediment, and constitute beds of marl, or by the slow absorption of mollusca be converted to shells. In the latter case, beds of limnææ, paludinæ, &c. are formed, and as generally the light argillaceous sediment entering such lakes is pretty equally diffused through the waters, the result is a bed of marly clay full of fresh-water shells. This process is daily going on, and in the course of a few years canals and river courses, as well as ditches and ponds, are choked by the abundant accumulation. In this manner, aided by occasional inundations, bringing layers of vegetable matter, or the detritus of the neighbouring country, have many old lakes become entirely filled up, and when cut open for any purpose, present layers of peat, clay, shell, marl, and sand, a faithful image, on a small scale, of those great fresh-water deposits which mark the force and extent of ancient currents on the surface of the Earth.

Deltas. The delivery of the sediment of rivers into quiet, tideless, land-locked seas is almost perfectly analogous to what happens in a large lake, but according to variation of circumstances, as the river flows into the open ocean, and contends with strong tides and sweeping currents, or disembogues itself into a gulf, enters deep or shallow water, the disposition of its sediment is different. The most remarkable deltas at the mouths of rivers are formed round such as empty themselves into tideless seas, as the Mediterranean, Black Sea, Caspian, Baltic, &c., or into comparatively quiet bays of the ocean, as the Bay of Bengal, the Gulf of Mexico; and the least effects of this nature are occasioned on coasts which are subject to be raked by lateral currents of the sea.

Most of the great rivers which enter the Mediterranean are daily increasing their deposits along the coasts, and spreading a quantity of sediment over the general bed of the sea. The Mediterranean has been proved by a line of soundings on the Skerki shoal from the African to the Sicilian coast, varying unequally from 7 to 91 fathoms, to be divided into two basins. In the Western portion, near Gibraltar, the bottom, consisting of sand and shells, has been reached at 5880 feet, and in the Straits at 4200 feet. Almost under the shore at Nice the depth is 2000 feet; but in the Adriatic, where it receives the sediment of the Po and other rivers, in the upper part, the greatest depth is 22 fathoms. Yet from the abrupt borders of the hill ground within the area of the sedimentary land, it is inferred that the Adriatic must formerly have been a deep gulf.

Nature of the deposits in gulfs, estuaries, &c.

Further from the influence of the rivers the depth increases considerably. Donati, on dredging the bottom of the shallow portion of the Adriatic, found it to consist partly of mud, and partly of calcareous rock, enclosing shells, which are sometimes grouped in families. (Lyell, 237.) The form of these sedimentary deposits must be what in common language is called horizontal, the substance of them fine clay and calcareous matter with shells, and as the ratio of accumulation is nearly uniform, there will be little appearance of strata, unless the calcareous deposits be accomplished at intervals. If by any effort of subterranean forces this bed of the Adriatic should hereafter be elevated, and made dry land, as so many other extensive tracts along the borders of the Mediterranean have been, we should have an argillaceous deposit extremely similar to the London clay, and perhaps identical with the subapennine marls, except by some difference of organic remains, and of such an extent as would appear incredible to those who believe in the almost quiet slumber in modern times of the mechanical and chemical forces which belong to our Globe. The same conclusions might be derived from an examination of the mouths of the Rhone, Volga, Danube, Ganges, Euphrates, &c. which enter the sea under the same favourable circumstances, and transport enormous quantities of fine sediment into comparatively tranquil and now shallow waters. A river like the Mississippi, which hurries an enormous volume of deep waters, and preserves its velocity to the edge of the sea, discharges likewise a prodigious quantity of matter, which settles round its many mouths into a vast and growing delta. But the kind of matter here deposited, and the mode of its arrangement will be different. Forests matted together by the growth of Ages, with all their foundations, their alligators, and other inhabitants, are swept down by this mighty stream, and either retarded for a time among its winding and variable channels, or hurried into the sea, and there, with quantities of similar matter, agitated, and partially or completely separated into beds of earthy and vegetable matter, the latter varying according to the prevalence of the many rivers which unite in the great stream, and thus the Gulf of Mexico is now filling with deposits, which in no feeble degree emulate our old carboniferous strata. We are informed by Mr. Lyell, whose volumes are full of valuable information on all subjects connected with the modern operations of natural agencies, that a great part of the new deposit at the mouth of the Rhone consists of calcareous and arenaceo-calcareous rock, containing broken shells of existing species; and Captain Smyth ascertained that over the broad, very gently inclined bed of this growing delta, marine shells were occasionally drifted by a South-West wind. In this way alternations of fresh-water and marine shells may be occasioned, in which the marine portions will predominate towards the sea and the fresh-water part be most decided toward the land.

The shorter and more rapid the course of a river, the larger and coarser is the sediment which it may be able to transport. While the Po, relenting in its velocity, leaves its gravel where it joins the Trebia, West of Piacenza, 130 miles from the sea; and the Ganges 180 miles above the commencement of its delta, and 400 miles above the present line of coast; the rough bed of the Yorkshire Tees is pebbly quite down to the sea; and the streams which descend by a short and furious course from the Maritime Alps bear down pebbles into the Mediterranean.

From these instructive examples of pebbly, sandy, argillaceous, and calcareous strata, forming at the same era, in different basins of the sea, and even in different parts of the same basin, enveloping entirely marine, entirely fresh-water, or a mixture of marine and fresh-water deposits, we may turn with advantage and pleasure to the contemplation of the older strata of conglomerate, sandstone, clay, marl, and limestone, and by carefully noting the points of agreement and circumstances of difference, may frame very satisfactory notions of the conditions under which they were deposited respectively. Especially we may be guided in our decision concerning the extent and connection or separation of the several basins of the ancient Ocean, and the relative influence of ancient and modern rivers.

Bars at the mouths of rivers.

Rivers which discharge themselves into the sea, where tides and currents contend with the freshes, may, as the Rhine, be enabled for a certain time to deposit their sediment in a Delta, and to increase this even to a vast degree, in consequence of their entering at a deep emargination of the coast, or amidst shallow sands which impede the action of the tide. But in such a case, the accretion of land must gradually diminish, and at length the movements of the sea must balance the current of the river. In this case a line of sand-banks will be formed varying in position according to the alternate predominance of the contending forces, and the entrance of the river will have a bar. The Rhine, the Thames, and all the Eastern rivers of England are nearly in the same case. The sea, indeed, has again reclaimed from the Rhine, by most destructive floods, the large spaces of the Zuyder Zee and the Bies Boos.

Thus also the growth of the Nilotic Delta, once so rapid, is greatly retarded or almost annihilated by a current of the Mediterranean; and the rivers of Western Africa, as well as the mighty Maranon, no longer extend themselves into the sea, but meet its currents in furious strife, drop the sand at their mouths, and resign their finer sediment to the disposal of the conqueror. The distance to which the Ocean can waft this sediment on its surface along with fresh water is very great. Captain Sabine supposes himself to have crossed the discoloured waters of the Maranon 300 miles from its mouth, where it still retained its comparative levity, and kept its place on the surface of the sea.

Thus may the sediments of distant Countries be mixed or alternately deposited far from shore, and even in the deep sea, a fact of great interest to Geology. The distinctness of currents of water which flow down the same river channel, even with a rapid descent, has often been noticed. Thus the Arve and the Rhone flow far without mixing, the Nahe takes one side of the Rhine, and even in the mining districts of England, the discoloured streams from the different valleys can often be distinguished along considerable lengths of the united river.

We shall not further extend our remarks on this subject than by stating a few instances of the actual surface of the Deltas of great rivers. The whole area of the dry Delta of the Po and the Adige, and other rivers which contribute to the effect on the same line of coast, must exceed 2000 square miles, and within the last 2000 years a space of 100 miles in length, and from 2 to 20 miles in breadth, has been added to the land. The area of the Nilotic Delta is about 12,000 miles, and according to Girard the surface of Upper Egypt has been raised by the sediment since the Christian era 6 feet 4 inches; of the Rhone 1500 square miles; of the Quorra 25,000 square miles. (Dr. Fitton, *Geology of Hastings.*)

The Delta of the Ganges, without reckoning that of the Brurampootra, which has now become conterminous, is considerably more than double that of the Nile, and its head commences at a distance of 220 miles in a direct line from the sea. The base of this magnificent Delta is 200 miles in length. (Lyell.)

The fen lands of Lincolnshire, Huntingdonshire, and Cambridgeshire occupy 1000 square miles, and the levels in connection with the Humber 300 or 409.

It has been attempted to deduce the age of our continents for the rate of increase of the Deltas of rivers within the Historic era. Thus the Nile was supposed by Herodotus to have formed Lower Egypt; and he states that if diverted into the Red Sea, it would fill that gulf with its deposits in less than 20,000, or even 10,000 years. Since the time of Herodotus it is supposed that the increase on the Nilotic Delta has been upon an average, one mile and a quarter. The average annual growth of the Delta of the Po, opposite Adria, which was once on the edge of the Adriatic, was, from 1200 to 1600 A. C., 25 metres, and from 1600 to 1800, 70 metres; a very rapid increase of rate, probably connected with the increasing shallowness of the sea. (Lyell, *Principles of Geology.*)

But all inferences from observations of this nature, and similar ones on the shallowing and conversion to land of the upper ends of lakes, can lead only to merely speculative results without the knowledge of a datum very difficult to be obtained, *viz.* the original depth of the sea, at all points over which the river sediment has flowed; for it is not by the *area* of the Delta, but by the *cubic content* of the sediment transported that the time occupied in the process is to be ascertained. How is this to be determined?

The Sea.

As the action of rivers is of two kinds, erosive and transporting, so is that of the sea. In one place its fury excavates the cliffs, and devours a whole country, in another every tide adds sediment to a growing shore, lengthens the fields, and extends the parishes, till what was once a broad bay becomes a fertile marsh, and the town which was once a flourishing port is far removed from the waves, and never visited by commerce. These different effects depend principally upon the circumstances under which the earthy materials are presented to the waters.

Wasting of Cliffs.

Cliffs exposed to the sea are either slowly decomposed by its vapours, and crumble piecemeal, or undermined at the base, and so caused to fall in ruinous heaps. Even the hardest rocks that begird the Ocean are more or less wasted away by its never-ceasing attacks, conjoined with the common atmospherical agents. Soft places are scooped into caverns, joints are widened, and blocks loosened, and thus, by little and little, every high coast recedes and yields more or less ground to the insatiable waves. But cliffs composed alternately of softer and harder strata, especially if there be any dislocation, are quickly eaten away, and still more rapid destruction falls annually on the crumbling diluvial clays and loose gravelly cliffs which margin so great an extent of the coast of England. The whole of the English coast may be cited for cases of this important wasting of the cliffs, and in particular the diluvial cliffs of Yorkshire and Norfolk. In the former County it seems to be ascertained, by careful measurements at many points, repeated after intervals of many years, that the annual loss of land on the whole length of Holderness, is not less than 2 yards in breadth annually. The average loss on the coast of Norfolk between Weyburn and Theringham is about 1 yard per annum, on the coast of Thanet 2 or 3 feet.

Extension of Marsh-land.

But these same coasts likewise exhibit, on an equally grand scale, the formation of *new land* from the materials thus detached from the old. The materials which fall from the cliffs are sorted by the tide, and according to their bulk and weight are differently disposed of. As in many artificial processes of washing powders the sediment is divided into parts of different fineness by merely shaking it at different distances or depths in the stream of water, so it is in the great currents of the sea. Large stones remain a long time at the foot of the cliff from which they fell, smaller masses yield something to the impetus of the waters, sand and pebbles are drifted along the shore according to the set of the tide, and collected into bays and hollows of the coast, or deposited in a line of moving beach; but the finer clays are transported far away in the waters, and allowed to settle only where these rest in land-locked gulfs, stagnate over weedy marshes, or lose their force in contest with the freshes. The breadth of the sandy beaches thus accumulated is often very great, even many miles of slow and regular descent. The sand-banks which stretch out so far from the low coasts are often regarded as remains of ancient lands overwhelmed by the sea, but in most cases they are probably recent formations, accumulated by the waves from the spoils of other regions. But what is thus left by the sea under some circumstances, may be again reclaimed by it under others. The once fertile district called North Friesland, most probably accumulated by the sea, measuring from nine to eleven geographical miles from North to South, and six to eight from East to West, was in 1240 entirely severed from the continent, and in part overwhelmed. The Island of Northstrand, thus formed, was, towards the end of the XVIth Century only four geographical miles in circumference, but still was richly cultivated and populous. At last, in 1634, in one night, the 11th of October, a flood passed over the whole island, whereby one thousand three hundred houses, with many churches, were lost, fifty thousand head of cattle and above six thousand men perished. Three small isles alone remain, and they are still further wasting. (Lyell.) It may often be remarked that substances thrown into the sea are not carried down at once to its depths, but rejected many times to the shore, in the direction of the tidal currents. This happens especially with all light, small, and easily moved bodies; but the case is different with the large blocks of stone, which, continually pressing by their weight downwards, are for the most part gradually withdrawn from the base of the cliff sunk in the beach, and rolled down to the deep.

In this manner, when the circumstances admit of it, the whole coast is in motion, every high cliff wastes away, the low grounds stretch out, the beach widens and again contracts, shifts upwards and downwards, and travels along, and thus amidst the extremes of constant fluctuation and change, new deposits are continually added to the quiet depths of the sea, and to the lowest parts of the land. As far out as the fluctuations of the waves can influence the bottom of the sea, the new deposits, where uninfluenced by currents, must become nearly horizontal; in greater depths it seems reasonable to suppose that the materials will be arranged nearly as in deep lakes; and under the cliffs, the beach being only at intervals exposed to the rush of ascending and descending waves, must have its surface inclined at corresponding angles.

We have no accurate data on which to found an opinion concerning the utmost depth to which the influence of the superficial undulations of water may extend. The influence of the tidal and other *currents* of the sea must extend to a great depth, and tend to equalize into nearly horizontal strata the loose materials collected from the waste of the land.

Coral islands, &c.

These extensive deposits of sand and clay are, however, not the whole of the productions of the sea. The Ocean indeed is but a large lake, and, besides the mechanical effects on its borders, is subject to various chemical changes, and to the unceasing agency of the functions of Organic Beings. Into that vast repository there flow annually great quantities of soluble matter of various kinds, and it is quite conceivable that by the interchange of their elements some chemical deposits may happen. It is also not unreasonable to admit that many exhalations rising from the bed of the sea may cooperate in such effects. But there is one ascertained cause incessantly in operation which probably occasions more extensive and permanent precipitation of carbonate of lime than any other process, the growth of zoophyta, shells, and crustacea. However small may be the quantity of calcareous matter suspended in water, the molluscous and zoophytic animals, which require such matter for their stony supports, are sure to possess themselves of it; and as corals and shells remain when their tenants dissolve away in the water, the bed of the sea is continually receiving important additions from this source alone. Besides these, the cast shells of crustacea, the teeth, and sometimes the skeletons of fishes and cetacea, must contribute no mean quota to the growing stock. It is perhaps yet an undetermined question to what depths in the sea light and the vital influence of the atmosphere can sustain the growth of plants and animals. We may, however, safely believe that the extreme gulfs of the sea are as devoid of organic life as the central solitudes of a sandy desert, while the borders of the one, and the shores of the other, teem with innumerable forms of life.

It was formerly supposed that those immense reefs of coral which divide the waters of the Pacific Ocean, and rear themselves above the waves into associated islands, arose from the deepest parts of the sea, in perpendicular walls. But many observations by Captain Beechey and other navigators, upon the crater form which the coral islands generally assume, and the volcanic rocks upon which they are frequently based, have produced a very general impression that the polypean races do not exist except at moderate depths. Captain Beechey found the coral of Ducies Island to be forming at a depth of one hundred and eighty feet.

The quantity of carbonate of lime thus produced by the coral animals, with the addition of shells, &c. enveloped by them in their progress, is really enormous, and might almost justify those Geologists who think that our stratified limestones are wholly derived from comminuted shells and zoophytes. A great proportion of all the low islands in the South Pacific Ocean is the work of zoophytes, and new islands are daily in progress, and submarine reefs of so great extent that Captain King found a continued line of coral reef 700 miles in length, from the North-East coast of Australia towards New Guinea. It was interrupted only by a few intervals not exceeding in the whole 30 miles in length. These reefs consist in great part of compact limestone, and Mr. Lyell compares them to the ancient calcareous rocks of the basins of Europe and North America.

This comparison, so just as to quantity of material, must not be extended to the structure and arrangement of the several masses. The rocks of carboniferous limestone have indeed derived a large part of their materials from the calcareous secretions of polypean and molluscous animals; but the materials can have been put into their present stratified form only by the ordinary mechanical action of water upon them. A modern coral reef might, by long movement in water, be ground up into something like a limestone bed, but the sharpness of the angles of the ornamented fossils of all the old calcareous strata appears to disclaim such an origin for these rocks. At the same time it is to be observed that the corals and other zoophytic reliquiæ, which abound in some of our limestones, very seldom appear to be in their ordinary places of growth, but rather seem to have been subject to some drifting. The corals may therefore in ancient times have grown in reefs, as at present, and this may perhaps be the reason of their irregular and unequal dispersion in the rocks—a fact particularly remarkable in the coralline oolite.

CHAPTER III.

DESCRIPTION OF THE ROCKS PRODUCED BY IGNEOUS AGENCY.

Introduction.

In the preceding Chapter we described the series of aqueous deposits which contribute to form the crust of the Globe, commencing our account with those of the earliest date, and terminating it with the consideration of the most modern.

In the present Chapter a similar order cannot be observed, inasmuch as in the case of the igneous formations which it becomes our next business to consider, we do not possess those criteria, derived from the order of superposition, and the nature of the imbedded fossils, by the aid of which we were enabled to determine in the former instance the question of relative antiquity.

Neither, indeed, are we entitled to take for granted *in limine* the igneous origin of all the rocks which will fall under our review, seeing that some of them have, until very recently, been attributed to causes of quite a different character, and that even at the present day they are regarded by some Geologists as of questionable formation.

It will be more satisfactory, therefore, in the present Chapter, to reverse the order of arrangement adopted in the preceding one; considering in the first place those operations of an igneous description which are going on in the interior of the Earth at the present day, tracing the effects which have arisen from similar causes operating during the historical period, and thus gradually ascending to the consideration of such apparently analogous phenomena, as may seem referable to those same agencies, acting at a still more remote era, and under circumstances in some respects different.

In this manner, we shall be best enabled to pronounce upon the origin of such rocks as deviate too widely from the structure and constitution of the products of igneous action which we see at present forming, to be referred at once and without examination to the same cause, and which, whatever may be their exact date, are at least not seen to be produced by causes now in operation.

Proceeding, then, from the known to the unknown, referring in the first instance all that is possible to existing agencies, and preferring to explain the remainder, by assuming a greater intensity of the same forces, rather than the influence of others of a different kind, we shall consider it our primary object to treat of volcanos at present in action; these being confessedly the most powerful and widely diffused of the igneous agents which are at work.

We shall therefore inquire, what phenomena, observed to take place under present circumstances, may reasonably be attributed to such a cause; and if it should appear, that all the changes of any importance going on on the Earth's surface which remain to be discussed, may without difficulty be referred to its agency, our task will then be greatly simplified, inasmuch as it will be limited to the consideration, in the first place, of existing volcanos and their consequences, and secondly of those which are extinct; after which we shall proceed to inquire into the nature of those granitic rocks and of others, which have protruded themselves, at different, though always at epochs antecedent to the present, through the aqueous deposits which compose the crust of the Globe.

PART I.

ON ROCKS PRODUCED BY IGNEOUS OPERATIONS OF A SIMILAR NATURE TO THOSE NOW TAKING PLACE.

SECTION I.

Description of Volcanic Phenomena in different Parts of the World.

General Notion of Volcanic Action.

If we contemplate a volcano whilst in a state of vigorous action, the phenomena presented to us are at once so peculiar and so impressive, that it would seem unnecessary to be at the trouble of defining that, which the commonest observer could hardly fail to recognise again, in whatever part of the Globe it might fall under his observation.

The evolution of smoke and ignited matter from an orifice in the Earth, generally situated on the summit or flanks of a conical mountain, the ejection of fragments and scoriæ, bearing a near resemblance in their condition and aspect to the slag of an iron foundery, the sudden and copious extrication of elastic fluids, with their natural concomitants, noise and a concussion of the rocks through which they force their way, are circumstances which strikingly impress upon the imagination the paroxysms of volcanic action, and appear to distinguish this from all the other operations of Nature.

Accordingly from the earliest periods the existence of volcanos had excited attention, and their leading phenomena were pretty correctly described. They have supplied a groundwork for the superstitions of the vulgar, and for the speculations of the philosopher, and much of our present knowledge with regard to the character, extent, and date of their operations, may be collected from the incidental notices of them, transmitted to us by the Historians, and even by the Poets of antiquity.

Nevertheless, when we examine the subject more attentively, difficulties occur with respect to the real relation borne by them to several of those phenomena, which from some obvious feature of similarity have been regarded as their offspring.

If, in conformity to the vulgar idea, all *burning* mountains are ranked amongst volcanos, we admit into the same class a variety of incongruous appearances, which possess indeed no one character in common, except that of being accompanied, with what seems at least to be an emission of flame, and which are therefore assignable in all probability to causes of many different kinds. If, on the contrary, none, but such as present this obvious resemblance to existing volcanos, are to be included in our definition, we lose the advantage of considering a series of effects, evidently allied to the subject before us, and perhaps equally illustrative of its real nature.

How different, for example, are the eruptions of Vesuvius and Etna, in *kind* as well as in *degree*, from the emanations of gas and aqueous vapour, which proceed at times from the sulphureous soil at Macaluba in Sicily, from the foot of the Apennines near Modena, and still more remarkably, it is said, in Crim Tartary, and in the neighbourhood of the Caspian; or from the emissions of gas now observed at Pietra Mala, between Bologna and Florence, and the spontaneous fire (as it was believed to be) which in ancient times added to the superstitious reverence entertained for the sacred peaks of Parnassus.

On the other hand, if we consider the character of the phenomena exhibited, how intimate is the connection between the eruptions of Vesuvius and the earthquakes or hot springs in its vicinity; and, looking only to the nature and constitution of the mineral products, how impossible is it to draw a line between those which have *evidently* resulted from its eruptions in modern times, and many rocks in the contiguous country, where nothing of a volcanic nature has as yet been noticed as occur-

Phenomena attributable to Volcanic Action.

In order, therefore, to establish a sufficiently broad basis on which to ground any general conclusions with regard to the agency of this cause throughout Nature, it seems necessary to settle in the first place, what phenomena, independently of those more palpable ones which first occur to the imagination, are to be regarded as indicative of volcanic action, exerted under the same circumstances as at present, though, possibly, at a very remote period.

It is clear, that the date of the eruption, which gave rise to these effects, will be immaterial to our present purpose, provided we possess an equal certainty as to its reality: and we shall be entitled to avail ourselves of the evidence to be derived from extinct as well as existing volcanos, just as the traveller, who should endeavour to collect proofs of the existence of iron founderies in an unknown country, might be at liberty to infer their presence, not only in places where they were at the time established, but also wherever such accumulations of slag and scoriæ were found, as could only have arisen from the same formerly in operation.

Phenomena admitted to be Volcanic.

Now the circumstances, which may be held sufficient to substantiate the existence of volcanic operations, of a description similar to those now proceeding, are derived from three sources:

1. Indications of internal commotion; manifested in the ejection of heated stones and scoriæ, the emission of lava currents, and the evolution of aqueous vapour, together with certain gases hereafter to be described.

2. The structure and appearance of the masses taken collectively; namely, the existence of a mountain approaching to a conical form, and composed either wholly, or at least superficially, of strata, possessing what is called a quaquâversal dip, or sloping away in all directions from a common centre, where some vestiges at least remain of a crater-shaped cavity.

3. The condition of the individual rocks themselves; namely, the presence in them in a greater or less degree, of a vitreous aspect and cellular structure, with a corresponding chemical constitution, in which some of the combinations of silica with the alkalies and alkaline earths form the prevailing, or, at least, the most constant ingredients.

Now we have no evidence, that either the mechanical or chemical characters above described have ever resulted from aqueous solution, whilst both the one and the other are familiar to us, as the effects, not only of volcanos, but also of artificial heat.

Without, however, pretending in this stage of the inquiry to assert, that the constitution of the mineral masses above assigned is sufficient in itself to establish the action of heat, we may be justified in concluding, that where it is conjoined with the cellular structure and glassy aspect alluded to, it may fairly be assumed to owe its origin to volcanic operations. In many, indeed, of those of modern date, the cooling appears to have been too rapid, to allow of any crystalline arrangement of the constituents taking place; and in a still larger proportion, though numerous crystals of augite, hornblende, and other minerals, may be disseminated, yet the basis of the rock cannot be identified with any known mineral or mixture of minerals, though apparently made up of augite and felspar in various proportions, and consequently presenting all shades of colour from grey to black. In these cases, the vitreous character, which more or less completely belongs to the rock, is sufficiently conclusive as to its origin, but the mineral composition can only be inferred from analogy, at least by common observers, who want either the patience or adroitness to adopt the mechanical method of examination, by which M. Cordier, it is said, contrives to separate and distinguish minerals too intimately blended to be recognisable by the eye or the lens. Indeed, the very employment of this method presupposes a certain confused crystallization, and is, by M. Cordier's own confession, inapplicable to many volcanic products, which, after having undergone fusion, were placed under circumstances precluding any new arrangement of the particles from taking place. Yet, wherever this is not the case, or what, practically speaking, comes to the same thing, wherever the component minerals are not too much blended together to be determinable, we generally find, that the basis of the rock is of a felspathic nature, rendered porphyritic by the presence of crystals, either of the glassy variety of felspar, or of some mineral of the hornblende or pyroxenic families.

The presence of the two latter, in sufficient quantity to impart their characters to the mass, stamps it as belonging to that class of volcanic products which has been denominated basaltic, and distinguishes it from the more purely felspathic kind, in which such ingredients are only of scanty and partial occurrence.

The latter class of ignigenous products, which consists for the most part of compact felspar, with crystals of glassy felspar imbedded, (owing to the harsh and gritty feel belonging to most of its varieties,) has been denominated trachyte, from the Greek word, (τραχυς, rough;) it has been observed by Von Buch and Humboldt to form, as it were, the basis of many existing volcanos, and even constitutes the material of certain lavas apparently of modern formation.

Amongst extinct volcanos, many entire mountains, and even vast tracts of country appear to be composed of this rock, which, whilst it passes on the one hand into clinkstones and phonolites similar to those occurring in the trap formations, graduates on the other into the species of volcanic products above alluded to, in proportion as crystals of augite and hornblende begin to be superadded to those of glassy felspar, which are essential to it.

The second class of volcanic products, distinguished by the predominance of these minerals, has been denominated by Mr. Scrope greystone; and as this term has a more English cast than the corresponding one, *tephrine*, which M. Brongniart had imposed upon rocks so constituted, it may be convenient to adopt it.

The greater part of modern lavas, whose constitution can be made out, appear to be composed of this species of rock, which is of course divided into a number of varieties, by the presence of sundry accidental ingredients, such as olivine, mica, titaniferous iron, and the like. In one or other of these classes, all volcanic rocks may probably be arranged which possess any discernible mineral structure; and those, in which fusion and rapid cooling has obliterated all traces of this kind, may nevertheless be referred with some degree of probability to one or the other.

Thus the pearlstones and the white pumices appear, from their chemical composition, as well as their external aspect, to be derived from trachyte; the absence of the materials of augite and hornblende being evinced from their not containing iron; whilst the obsidians and the lithoid lavas generally partake of the character of greystone, the proportion of *oxide* of iron serving to show (even where their mineral structure is undiscernible) that augite has contributed to their formation. The same remark, indeed, applies to the case of *basalts*, properly so called; and the difference of structure which is discernible in passing from the obsidians to the true basalts, between which the different varieties of modern lavas seem to be, as it were, the connecting links, indicates, that they have been all derived from some common matrix, which, after having undergone fusion, had cooled under different circumstances.

The only exception to this, is the larger quantity of alkali present in certain obsidians than in basalts and lavas; a circumstance which may, perhaps, enable us to explain, how it happens that this mineral, which we are disposed to attribute in general to sudden cooling, shall nevertheless be found occasionally to constitute streams of considerable size and thickness, where we might therefore expect lithoidal lava to have been produced.

The rocks above noticed may each of them exist under several different modifications of form and aspect; they may occur, either as loose, detached blocks, ejected, probably, in a solid, or, at least, a semi-fluid state from the crater, or as the constituents of a kind of tuff; fragments of various sizes being imbedded in a sort of loose iron-clay or sand, denominated puzzolana; or, lastly, they may constitute a bed of lava, which once issued in a continuous stream from the interior of the volcano, whilst in a state of vehement activity.

To give to such materials in all the above cases the name of lava, as some Geologists have chosen to do, is obviously incorrect; this term having reference, properly speaking, not to the particular constitution, chemical or mechanical, of the mass, but to the mode of its ejection from the volcano; and being, therefore, improperly applied to rocks which appear to have been projected in detached fragments into the air, and never to have formed part of a current of melted matter.

We likewise coincide with Mr. Scrope in condemning the limitation of the term trachyte to felspathic rocks of a particular age and position, thus excluding those lavas which possess corresponding mineral characters. That rocks agreeing altogether in mechanical structure and aspect with the trachytes of tertiary formations are uncommon amongst the older rocks, may, indeed, be true; but to lay down as a rule that the porphyries of one particular age are alone to have this title, is to prejudge the question, and to proceed on quite a wrong principle in framing our nomenclature.

Division of Volcanic Products according to their relative Ages.

Volcanic products have been distinguished by some Geologists according to their relative antiquity; those which appear to have been ejected antecedently to the period of the excavation of the contiguous valleys being denominated *antediluvial*, and those of subsequent ejection *postdiluvial*. Others have objected to this distinction as involving an hypothesis; since, as we have seen, it is still a question of debate whether valleys of denudation have been produced by short periods of general convulsion, or by the continual operation of rains and torrents, acting with only their present force and violence. Perhaps, however, the terms may still be admitted by Geologists, of whatever school, with the same mental reservation, as that, with which many have been in the habit of employing the corresponding ones, of diluvial deposits, diluvial gravel, and the like. They serve to distinguish the relative antiquity of the rocks so classified, with greater precision than the terms of *ancient* and modern, which it has been proposed to substitute, since they refer to a definite standard, which leaves no doubt in the mind as to the sense in which we *employ the word* antiquity in our Geological language.

Without some such understanding, indeed, the volcanic rocks in Auvergne might be called ancient, with reference to those of the Vivarais, though they are modern when compared with others in their own neighbourhood; whilst in either point of view they must be regarded as postdiluvial, since their relation to the valleys of the country is such, as to prove, that no great changes have taken place in the configuration of the surface, since they were ejected.

Even if it be true, as Mr. Scrope contends, that there are lava currents in some of these volcanic districts, as in Auvergne, which appear to be antecedent to some of the valleys of the country, and posterior to others, there will still be nothing to preclude us from applying the above denomination to cases in which this cause of uncertainty does not exist.

Postdiluvial Volcanic Rocks.

Now the importance of distinguishing the relative ages of volcanic rocks, in the manner above proposed, will be evident from considering, that the two classes commonly differ one from the other in aspect and structure. The postdiluvial volcanic products having, in almost all the cases in which they come under our examination, been ejected in the open air, and, consequently, for reasons which will be afterwards explained, having in general cooled more rapidly, present for the most part a harsher feel and more of a vitreous aspect; whilst from the character of their component masses, even more perhaps than from the shorter period, during which their surfaces have been exposed to atmospheric action, they are but partially covered with soil, and admit, consequently of but a scanty and inferior pasturage.

For the same reason, they consist more commonly of those volcanic products, in which the constituent parts are blended together so as to be undistinguishable, though from their general appearance, and from the character of those portions in which the mineral composition may be discerned, it would appear, that basaltic lava or greystone predominates over the purely trachytic, in those modern volcanos with which we are best acquainted.

Antediluvial Volcanic Rocks.

The antediluvial volcanic rocks, on the contrary, are not only characterised by valleys of precisely the same kind as those which intersect the contiguous country, but likewise, by a greater tendency to crystallization in their constituent parts, by a greater predominance of felspar, by the occurrence of masses sometimes in no way distinguishable from the basalts and greenstones of the trap formations, and still more frequently exhibiting a nearer approach to them, than is observable amongst the products of igneous action at the present day. Though frequently cellular, their cells have not that glazed internal surface which characterises many modern lavas, and are usually more or less completely filled with crystals of carbonate of lime, zeolite, and other minerals, which are not so frequently found amongst postdiluvial lavas.

What variation in the circumstances under which the former were ejected could have given rise to these differences, will form a subject for future inquiry; at present it is only necessary to point them out, as a reason for distinguishing volcanic rocks into two classes according to their relative antiquity, those ages being determined, either by their shaping their course in conformity to the present configuration of the country, or being themselves intersected by the so called valleys of denudation. The opinion which may be entertained with regard to the origin of such valleys, will not materially affect the question as to the propriety of availing ourselves of such a distinction; since the vast difference, between the width and depth of the valleys which in many cases intersect the *older* volcanic rocks, and that of the ravines which evince the action of existing causes upon the *modern*, proves, that if the same agencies, operating with their present intensity, have produced the former, it can only have been after a lapse of ages beyond comparison greater.

In Auvergne, for instance, where the most modern volcanos appear to have been anterior to the Christian Era, the utmost amount of the excavation effected in them by present causes, is to produce a ravine or water-course, in some instances, indeed, as much as from fifty to seventy feet in depth, but still of very inconsiderable breadth; whilst the ancient volcanic rocks are characterised by valleys possessing the easy and gradual slope of those which belong to the older rocks of the country, and like them, often many hundred feet in depth, and perhaps a mile or two in diameter. Another important distinction in the character of volcanic products, depends upon the situation of the point in the Earth's crust on which the eruption breaks out, and in particular upon its occurrence either in the open air or under deep water. We say, deep water, because in shallows no great influence could be expected to be exerted, and the phenomena would therefore resemble those which take place in air. But, between the nature of products arising from the same volcanic action, under the pressure of only one, or of a thousand atmospheres, considerable difference might be anticipated; and hence it becomes proper *in limine* to mark the distinction designating the former class of volcanos as *subaerial*, the latter as *subaqueous*. The characters of these two classes will be considered afterwards; but in the first place we will proceed to give a brief description of the principal foci of volcanic action distributed over the face of the Globe, conceiving, that by so doing, we shall enable our readers to obtain a better notion of the general character of the phenomena themselves, than could be gathered from any more abstract account of them.

We shall, therefore, begin with the vicinity of Naples, not only as supplying us with one of the longest known, and best described instances of volcanic agency that exist, but likewise as exhibiting these phenomena under all their various phases of activity, contrasting the effects produced in earlier periods of the World with those going on at the present.

Vesuvius.

To the East of the Bay of Naples rises the most recent of the volcanos met with in that neighbourhood, and the only one at present in complete activity.

The date of that part of the mountain properly called Vesuvius, or rather of its cone, perhaps does not go further back than the period of the famous eruption of A. D. 79, in which Herculaneum and Pompeii were destroyed; for the ancient writers never speak of the mountain as consisting of two peaks, which they probably would have done if the Monte Somma had stood, as at present, distinct from the cone of Vesuvius.

Other facts might be also mentioned to show, that the old mouth of the volcano occupied the spot now known by the name of the Atrio del Cavallo, but that it was greatly more extensive than that hollow, comprehending likewise the space now covered by the cone, which was thrown up afterwards, in consequence of the renewal of the volcanic action that had been during so many ages suspended. This spacious crater was probably the spot in which, according to Florus and Plutarch, Spartacus and his Gladiators were besieged by the Roman General Clodius Glaber.

We infer from the account given, that the brim of the crater was entire, except in one part, by which the insurgents had entered, and which the enemy kept closely guarded; and the great steepness of its sides is evinced by the scheme which the besieged party were compelled to adopt in order to effect their escape; that, namely, of twisting into ladders the vine twigs that grew upon the top, and descending by means of them to the bottom, where they surprised the Roman Camp. Nor does this seem inconsistent with the account given by the accurate Strabo respecting the structure of Vesuvius in his time; namely, the fertility of its sides, and the barren flat which constituted its summit; this flat being in all probability the spot occupied by Spartacus, broken away on the side fronting Naples, but encompassed elsewhere by steep precipices, the relics of the original brim of its crater.

It appears then, both from the silence of ancient writers, and from the appearance presented by the mountain itself, that a long interval had elapsed since any indications of activity had been observed; and the first symptom of internal agitation given by the volcano was in the year 63 after Christ, when an earthquake occasioned considerable damage to many of the cities that had been built in its vicinity. But it was not till the year 79, that the first eruption of Vesuvius took place, of which any historical records exist. It overwhelmed the cities of Stabiæ, Pompeii, and Herculaneum, with showers of sand, pumice, and lapilli, and seems to have covered the latter to a still greater depth with a kind of mud eruption similar to those which are produced, not unfrequently, by the volcanos of South America. Such, at least, is the inference that has been drawn from the circumstance, that the former towns are covered only with strata of incoherent materials, little, if at all, affected by water, whilst the latter is buried in a kind of tuff, separated at intervals by strata of white volcanic lapilli. The depth at which Pompeii is overspread does not exceed 14 feet, and that at Stabiæ probably is nearly the same; whilst at Herculaneum the mass of tuff alone above the theatre is not less than 85 feet, over which, it is stated, occur 12 or 14 palms of common soil, and this is covered again by a true lava, probably of much more recent date. That the tufa was at first soft, is evident, from the impression of a woman's breast, and other parts of the figure being found in this volcanic deposit, possessing, it is said, a sharpness, equal to that of a cast in Paris plaster.

The difference between the substance which overwhelmed these cities, is evinced by the state of the papyri discovered in the houses, that have been since freed from the load of matter which had encumbered them. In those met with at Pompeii and Stabiæ, which are covered by a more uncemented congeries of sand and stones, decomposition has proceeded so far, that their contents are illegible, and the vegetable matter, it is said, has been replaced, by a grey, pulverulent tuff, probably washed into them by the rains of many centuries.

At Herculaneum, on the contrary, though the manuscripts may have been carbonized, probably by the wet which first penetrated into them from this aqueous inundation, yet any further decay has been prevented by the thick covering of tufa, and the writing is, therefore, in many instances, found to be legible.

No lava appears to have been ejected by this eruption; but it is not improbable that a cone occupying the site of the present one may have been formed by it, and that the mountain thus exchanged the appearance which seems to have belonged to it at the time of Strabo, for one more approaching to that which it exhibits at present.

Of this memorable eruption we have a lively description in the letters of the Younger Pliny, whose uncle, the celebrated Naturalist, fell a victim to his zeal in exploring its phenomena. Yet it is remarkable, that no notice is taken, either by this eye-witness, nor by any writer who lived near the time at which the catastrophe happened, whose Works have come down to us, of the fate of three such considerable towns, although the testimony of Dion Cassius, coupled with that of Martial, serve to identify their destruction with this particular epoch.

The second eruption appears to have happened in the year 203, under the Emperor Severus, and is described by Dion Cassius and Galen; the third in 472, which is said by Procopius to have covered all Europe with ashes, and to have spread alarm even at Constantinople. Other eruptions are recorded in the years 512, 685, and 993. The next, in 1036, is supposed to have been the first which was attended with an ejection of lava; in preceding accounts we hear only of sand and lapilli being thrown out.

Between that period and the commencement of the XVIIth Century, the mountain appears to have been only five times in a state of action; and in 1611, the interior of the crater, according to the report of Braccini, was covered with shrubs, and every thing indicated the profoundest tranquillity. Yet in 1631 one of the most terrible of its eruptions took place, which covered with lava the greater part of the villages lying at its foot, on the side of the Bay of Naples. Torrents of water also issued from the mountain, and completed the work of devastation. The volcano is likewise said to have been in activity in the years 1660, 1682, 1691, and 1698, from which time till the present its intervals of repose have been of shorter duration, though its throes, perhaps, have diminished in violence; for the longest pause since that time was from 1737 to 1751, and no less than eighteen eruptions are noticed in the course of little more than a century, several of which continued with intermissions for the space of four and five years. That of 1737 gave rise to a stream of lava, which passed through the village of Torre del Greco, and continued its course until arrested by the sea, at which time its solid contents were estimated at 33,587,058 cubic feet. Of the latter eruptions, one of the most formidable seems to be that of 1794, recorded by Breislac, himself an eye-witness of it, in his travels through Campania. The torrent of lava, that proceeded from the volcano, again destroyed the town of Torre del Greco, and advanced into the sea to a distance of no less than 362 feet, with a front of 1127 feet.

The eruption of 1813 has been described by Menard de Groye, and that of 1822 by Monticelli and Scrope. According to this latter Geologist, the whole of the upper part of the mountain was on this last occasion blown into the air, by the violence of the explosive force.

It must be confessed, that these descriptions, however interesting, leave us much in the dark with regard to the real nature of the phenomena; partly from the danger and difficulty of approaching the scene of operations, near enough to examine the products at the time of their ejection, but still more, from a want of due chemical knowledge in the observers themselves, such as should enable them to profit by the facts before them.

On this account, the remarks of Gay Lussac and Sir H. Davy, cursory as they are, exceed in scientific interest the more elaborate descriptions given by others; and if we abstain from noticing them at present, it is only because the results of their inquiries will appear more in place, if introduced hereafter.

Phlegrean Fields.

It is important, however, to observe, that since Vesuvius has resumed its activity, the numerous volcanic vents which exist on the other side of the Bay, (see pl. vi. fig. 2.) have sunk into a state of comparative inaction; for ancient writers, who are silent respecting the former, speak of the mephitic vapours of the Lake Avernus, as destructive to animal existence; and in earlier days than these, Homer pictures to us the Phlegrean Fields, as the entrance to the Infernal Regions, being placed at the utmost limits of the habitable world, unenlightened either by the rising or the setting sun, with groves consecrated to Proserpine, and enveloped in an eternal gloom.

Solfatara.

At present the only traces of activity that exist, are observable in the crater called the Solfatara, which occurs immediately above the little town of Puzzuoli. The rock of which this volcano is composed, is a hard and dark coloured trachyte, for the most part porphyritic, and containing more iron than belongs to this rock in general. It has given off a single stream of lava, which descends in the direction of the sea, terminating in an abrupt promontory called the Monte Olibano, and remarkable, as an instance of a true trachytic lava, consisting of little else than felspar, only occasionally intermixed with augite. It has been conjectured that it was the fruit of an eruption in the year 1198, said, though on rather doubtful testimony, to have taken place from the Solfatara.

The crater of this volcano is nearly oval, its greatest diameter being 2337 French feet, its smaller 1800 feet; and the continual evolution of sulphureous vapours, which has gone on from the earlier records to the present time, has naturally produced remarkable changes in the rocks surrounding it. The first stage of alteration seems to be a mere whitening of the mass, in consequence, doubtless, of the removal of the iron, to which its colour is attributable; in the next the rock becomes porous and fissile; when the process is further advanced, it acquires an honey-combed and spongy consistency; and at length it crumbles into a white powder, consisting almost entirely of silex. The rocks surrounding the Solfatara have consequently that white colour, which has given to them, in ancient times, the name of Colles Leucogei; and the saline ingredients, with which those in the crater itself are impregnated, are natural effects of the action of the sulphuretted hydrogen emitted, upon the alkali, the iron, and the alumina, which were its constituent parts. That a mountain so circumstanced should possess numerous internal cavities, is only a natural consequence of the continual penetration of corrosive vapours during the course of so many centuries; so that we may save ourselves the trouble of inquiring, whether the hollow sound, which it emits when struck, might be produced by any other cause, when the porous nature of the ground affords us so simple a solution of it.

Monte Nuovo.

The throwing up of a new mountain in the XVIth Century by volcanic agency, took place so much in the vicinity of the Solfatara, that it may seem to belong to its history. After a succession of earthquakes, and, as we are told, the bursting out of flames from the ground, in many places round about the Solfatara, there opened from the sea a gulf, from which, smoke, pumice, lapilli, and sand, were ejected with the noise of thunder. These masses fell in such abundance, that the sand was distributed, not only over Naples, but even to a distance of thirty miles from it, whilst the heavier and more bulky masses accumulated round the orifice to such an extent, that in two, or at most in five days, they constituted a conical hill, now called the Monte Nuovo, 8000 feet in circumference, and 413 in perpendicular height, with an internal crater about a quarter of a mile round, and in depth nearly equal to the elevation of the mountain itself.

The sand near the foot of the mountain, even underneath the sea, possesses so high a temperature, when brought up from a point, a little below the surface which touches the water, that we are led to believe the volcanic action to be still going on to a certain extent; an inference confirmed by the extreme heat of the water which gushes out from the rock in a cavern not far distant, called the Baths of Nero, which is sufficient to boil an egg, and amounts, according to Mr. Forbes, who has given the most accurate account of it from personal inspection, to 183° of Fahrenheit.

Such are the principal indications of volcanic agency, that have been handed down to us by history, as occurring in the neighbourhood of Naples; but the physical structure of the country is such as leads to a belief, that similar phenomena must have occurred elsewhere, since the country acquired its present general configuration.

Grotto del Cane.

The Lake Agnano, from its circular form, and the nature of the materials surrounding it, was evidently the crater of a volcano, which still communicates heat to a spring of water on its borders, and, probably, causes that continual evolution of carbonic acid, which fills the well-known Grotto del Cane. The Lake Avernus seems also to be of similar origin; and although there are no indications of a volcanic nature existing in it at present, yet the term, *graveolens Aornos*, applied to it by ancient writers, and the noxious effects of its exhalations upon birds that skimmed over its surface, prove that, at a period not very remote, sulphuretted hydrogen was emitted in large quantities from its spiracles.

The Monte Barbara and Monte Astroni are hills, which, from possessing a central and circular cavity on their summits, as well as from their figure and mineral constitution, are evidently derived from volcanic operations, although neither of them appears to have emitted streams of lava. The crater of the latter mountain is still so perfect, as to form a sort of natural inclosure nearly a mile in diameter, appropriated by the King of Naples, as a preserve for his wild boar and other animals destined for the chase.

Many other craters are alluded to by Geologists, as occurring in the vicinity of Naples, but they do not appear to be sufficiently ascertained; and several so designated are evidently mere hollows, derived from the action of water upon rocks, which, though of a volcanic origin, are of an earlier date, and of a somewhat different formation.

Puzzolana.

The whole country, indeed, from the sea to the base of the *Apennines*, appears to have been covered, at a time when it was yet submerged under water, by an immense deposit of *puzzolana* or volcanic tuff. This rock is for the most part of a straw-yellow colour, dull, and harsh to the feel, with an earthy fracture, and a loose degree of consistence. It contains imbedded fragments of pumice, obsidian, trachyte, and many other varieties of compact as well as cellular lava, the softer kinds often rounded, the harder mostly angular. It is separated into beds, by intervening layers of loam, pumice, or ferruginous sand, and, in one instance, according to Von Buch, calc-sinter. Shells are noticed as occurring in it, but they are rare, and bones of ruminating animals have likewise been discovered.

The height of this tuff in many places near Naples is very considerable; the hill of the *Camalduli*, which rises to an elevation of 1513 English feet above the sea, consists of this material, and to the West of Naples it forms a sort of wall, so lofty and abrupt, that the former inhabitants of the Country apparently found it easier, availing themselves of the soft and friable nature of the stone, to cut through, than to make a road over it.

Such is the origin of the celebrated Grotto of Pausilippo, a kind of tunnel 363 toises, or 2178 feet in length, 50 feet in height, and 18 in breadth, which serves as the common medium of communication between Naples and the towns and villages to the West, said to have been originally formed by the Cimmerians, the earliest inhabitants of the Country, who dwelt chiefly in caves hewn out of the soft tuff, and were, therefore, led by successive steps to attempt more extensive excavations. The Romans appear to have merely enlarged, not to have originated it.

Now, though it need not be supposed, that this mass of tuff was originally deposited at equal depths over the whole surface which it covers, yet no one who examines the manner in which it has insinuated itself into the valleys, not only on the hills above Naples, as near Caserta, but also on the opposite side of the Bay, near Sorrento, and observes at the same time the extreme variation in its height, and the seemingly capricious manner in which it is distributed, can hesitate to suppose, that much which was originally deposited has been subsequently removed by the action of water; and, inasmuch as the general features of the country do not appear to have materially changed since the earliest periods of history, we are drawn to the alternative either of concluding, that the period, at which this mass was originally formed, goes back to a period beyond comparison more remote than that to which history reaches, in order to give time for causes at present in action to work such great changes, or that it has been effected by some more rapid agents of destruction than those at present at work. Either of these suppositions, it is clear, establishes a line of demarcation between the puzzolana and the volcanic rocks before enumerated, which is also confirmed by the indications we possess, that the latter was formed, whilst the greater part of the low country which it covers was still submerged under water.

But if, as seems obvious, the great mass of puzzolana near Naples has been deposited under water, the height above the level of the Mediterranean, which it not unfrequently attains, indicates the existence of great relative changes in the level of the sea and land, attributable either to a rise of the one, or a sinking of the other. The general consideration of this question belongs to another portion of the Treatise, but there are certain indications of a change of level in this district of so remarkable a nature, that it would be improper wholly to omit mention of them on the present occasion.

Temple of Serapis at Puzzuoli.

One of these relates to the appearances presented by a Temple near the town of Puzzuoli, supposed to be dedicated to Serapis, which appears to have twice changed its relative position to the sea contiguous, having been at some period subsequent to its erection sunk about twenty feet below its original level, and at some later period raised up again, nearly, though not altogether, to its former height. This inference is deduced from the circumstance, of the pillars which now remain erect, being perforated by pholades, at a height of about twelve feet from their pedestals, as if the sea had at one time stood at that elevation, which, it is evident, it could not have done at the time the Temple was built. Standing, as this fact appeared to do, alone, it was natural, that various hypotheses should have been suggested, in order to escape from so startling a conclusion, as that of the local rise and subsidence alternately of the spot of ground on which the Temple stood; but to such it is unnecessary to resort, now that we are assured or reminded of other proofs, showing an elevation of land at no remote period both on the North and South of Puzzuoli, of more than twenty feet, and of many similar subsidences to an equal extent in the same neighbourhood. Professor Forbes has the merit of first setting us right on this question, and his arguments have been extended and confirmed by Professor Lyell, in his recent Work, entitled *Principles of Geology* It therefore appears, that the effects of recent volcanic action have more than once altered the relative level of the sea and land in this neighbourhood, and we are, therefore, brought more readily to admit the possibility, that an extension of the same force, operating more generally, may have elevated the whole mass of the puzzolana, from the level of the sea, to the height at which it now appears.

Islands of Procida and Ischia.

To complete this brief sketch of the phenomena in the neighbourhood of Naples, we ought to allude to the Islands of Procida and Ischia, which belong to the same system of volcanos. (See pl. vi. fig. 2.) The former island seems to consist entirely of tuff, separated by beds of cellular lava, which are sometimes horizontal, and at others curved and contorted; but Ischia is somewhat more varied in its composition. It is for the most part composed of a rock which seems to consist of very finely comminuted pumice, reagglutinated so as to form a tuff. From the very fine state of division, however, into which it was reduced at the time when it underwent consolidation, a rock has often resulted of so homogeneous a texture, as to be considered a variety of felspathic lava, to which, mineralogically speaking, it bears a considerable resemblance, though we are, upon the whole, disposed to class it with the puzzolana of Naples, and the neighbouring Island of Procida. This formation is seen in every part of the Island, and forms the very summit of Monte Epomeo, which rises to a height of perhaps 2000 feet. In one spot, near the town of Foria, we observe intermixed with it huge blocks of trachyte, sometimes thirty feet in diameter, consisting of a congeries of crystals of glassy felspar, often without any kind of intermedium. In another, however, we observe a conical hill called the Monte Thabor, composed entirely of trachyte, and resting upon a bed of clay containing tertiary shells.

Ischia, however, presents evidence of volcanic operations of a more recent date, than can be assigned to those, which occasioned the formations above noticed.

Heaps of obsidian and pumice, substances almost unknown at Vesuvius, occur at the village of Castaglione, and have been traced by Spallanzani to a crater in the neighbourhood, called Rotaro. Still further to the East we cross the stream of lava, which issued from the side of the mountain in the year 1302, as we are informed by historians, remarkable for the large crystals of glassy felspar which are imbedded in it. Its surface is still undecomposed, and consequently barren, moss alone growing upon it, and that only in a few parts; a proof of the number of ages required for bringing some lavas of a vitreous nature into a state fit for cultivation. This current may be readily traced up the mountain to the point whence it issued, which is marked by the existence of a crater, still named the Capo d'Arso.

Thus Ischia appears to have been subjected to volcanic action of as many different periods as the neighbourhood of Naples itself, its pumiceous conglomerate corresponding with the puzzolana, its trachytes with the rock of the Solfatara, and the lava of the Capo d'Arso with that of Vesuvius.

At present, the only direct indications of volcanic action are seen in the high temperature of the sand on the shore near Monte Vico, which ten feet below the surface is equal to 110° of Fahrenheit, and in the hot vapour which issues from the ground in various spots of the same neighbourhood. No eruption of lava has taken place since the XVIIth Century, though occasionally severe earthquakes are felt over the Island, more particularly, it is said, near the ancient point of emission of the Ischian volcano. (Forbes.)

We have dwelt upon the phenomena exhibited by this particular system of volcanos, somewhat more in detail than may be consistent with our general plan, conceiving, that a better notion may be conveyed of the nature of such operations, by particularizing some one district in which they are exemplified, than by any more abstract or generalized description; and certainly no one spot can be selected more illustrative, than the neighbourhood of Naples, as well from the variety of appearances presented, as from the facility with which they can be examined and compared. We must now proceed to specify more briefly the other principal foci of volcanic action, that have at one time or other existed in Italy.

Mount Vultur.

On the Eastern side of the Italian Peninsula, in the Province of Basilicata, near Melfi, rises a large isolated hill, called Mount Vultur, which at one time appears to have been a volcano of equal magnitude with that of Vesuvius on the opposite coast.

It is of a conical form, from twenty to thirty miles in diameter at its base, and with two craters on its summit. It is studded over with sundry parasitical cones, and has given rise to several considerable streams of lava.

The nature of the rocks, and the gaseous exhalations that abound in its neighbourhood, bespeak the former prevalence of volcanic action throughout this country, and may lead us to regard the district, as bearing a similar relation to the shores of the Adriatic, which the Campi Phlegrei, as they are termed, do to those of the Mediterranean.

Yet of the eruptions of this volcano, all records are lost in the darkness of antiquity, and we may perhaps refer them to that remote period, when, as has been conjectured, the foot of Mount Vultur was washed by the waters of the Adriatic, which now, from an accumulation of alluvial matter, has receded full thirty miles from it.

Assuming then the space comprehended between latitude 40° and 41°, as that portion of the Italian Peninsula in which volcanic operations are most rife, we will, in the first place, trace the same appearances Northwards, and afterwards Southwards of this central point.

Rocca Monfina.

First, then, near Mola di Gaeta, on the road between Naples and Rome, we recognise on the main land, North-East of the town of Sessa, extensive traces of volcanic operations, a considerable mountain, called Rocca Monfina, composed of lava and scoriæ, and retaining vestiges of a crater, appearing to have overspread the whole adjoining district with volcanic materials. Some of these appear to have been ejected since the country was inhabited by man; for the remains of an ancient city have been discovered in digging underneath the town of Sessa, of which, however, as well as of the eruption that destroyed it, no record exists.

Ponza Islands.

A few miles out at sea, to the Westward of Mola di Gaeta, lie the Ponza Islands, four of which appear to be entirely volcanic, consisting of trachyte, but are destitute of any crater, and without any stream of lava proceeding from them. They seem, therefore, rather to have been suddenly elevated from the bottom of the sea, than to have been formed by successive ejections of volcanic matter.

Papal States.

A low tract called the Pontine Marshes, divides these volcanos from the series of rocks near Albano, which in their structure and figure appear to have the same origin.

Near Albano are no less than four lakes, which seem to have been formerly craters.

The immediate vicinity of Rome, commonly denominated the Campagna, is composed of materials, which, though of a volcanic nature, appear to have been heaped together under water.

They consist of loose masses of lava or scoriæ, feebly agglutinated by fine volcanic sand, and alternating with arenaceous or calcareous beds, containing fresh-water shells, which seem therefore to have been deposited at the bottom of a lake. Hence although certain obscure notices of volcanic phenomena that occur in the history of ancient Rome, may lead us to infer, that the forces had not altogether spent themselves at the time the country began to be inhabited, yet it seems probable, that the eruptions occurred principally at a more remote period, when the Campagna was covered with water, and the higher parts of the country alone constituted dry land.

Evident traces of volcanic operations of an early period occur near Viterbo, and extend Northwards to Radicofani, but we have no records of their date, and but imperfect accounts of their effects.

North of Italy.

Indications of the same nature exist probably further North in the neighbourhood of Volterra, where occur pools of water called Lagunes, rendered boiling by the passage through them of sulphuretted hydrogen, which carries with it a little boracic acid.

But less equivocal proofs of volcanic agency are found near the foot of the Apennines in the neighbourhood of Verona, Vicenza, and Padua.

Extensive beds of volcanic tuff there occur, alternating with deposits charged with shells belonging to the newer tertiary period, with which is connected a group of trachytic rocks, constituting the Euganean Hills, which have burst through chalk. Every thing concurs to prove, that the whole or the greater part of these rocks were formed during the tertiary period, and consequently that they belong to the more ancient or antediluvian class of volcanos.

Having enumerated the principal foci of volcanic action North of Naples, we must retrace our steps, and examine what indications of the kind are to be discovered to the South.

In Calabria, harassed as it has been by earthquakes, no genuine traces of volcanic agency have been discovered, but in the sea to the West of it occurs the group of the Lipari Islands, which are derived exclusively from this cause.

Lipari Islands.

These, however, although built up by the action of preexisting volcanos, appear at present in a great degree exempt from their influence; the only remaining indications of the kind being those presented, by certain hot springs, which in this case we cannot hesitate to refer to such a cause, by a Solfatara in one of the smaller Islands, that of Volcano, and by the volcanic eruptions of Stromboli. The latter differs from most other burning mountains in the unintermitting character of its eruptions, which have indeed continued, from a period at least antecedent to the Christian Era, at intervals of a few minutes, but without any ejections of lava accompanying them.

The great mass of this, as well as of most of the other Islands, is composed of beds of volcanic tuff or puzzolana, occasionally penetrated by dykes of slaggy lava, which sometimes traverse the contiguous beds in a manner so conformable to the stratification, that, until traced to some extent, they might be mistaken for beds. Then, indeed, they display their true character, either by the disturbance they occasion in the beds which they traverse, or by some deviation from their original direction. (See pl. v. fig. 1 and 2.) The peculiar feature of the volcanic products of the Lipari Islands, however, consists in the abundance of pumice and obsidian, two different states of igneous productions, but rarely, if at all, met with amongst the volcanos of Naples.

In the South of Lipari, the whole surface is covered with pumice, which forms several considerable hills, and extends to the furthest point of the Island.

The obsidian also occurs in extensive beds, or forming a sort of breccia, angular masses of it being held together by a white earthy-looking paste, which is hard and gritty.

Sicily.

The Island of Sicily contains a great variety of rocks of ancient formation, in which nothing of a volcanic nature can be detected; but, from a period comparatively recent, igneous and aqueous groups seem to have gone hand in hand, in building up the rocks of which its surface is composed.

In the lower extremity of the Island there occur various alternations of volcanic with neptunian deposits, constituting a considerable tract, containing within it hills from one to two thousand feet in height. The volcanic rocks, though sometimes compact, are usually more or less cellular. The cells are occasionally empty, but at other times are filled with various crystalline minerals. The neptunian, according to Professor Lyell, contain marine shells, the greater part of which are identical with existing species, though a few are extinct, belonging to the newer pleocene era. Hence the volcanic eruptions, of which Sicily affords the records, numerous and extensive as they are, do not go back to an era more remote than the newer tertiary deposits. The great *marly* formation, indeed, which occupies a large surface in Sicily, and is characterised by immense deposits of sulphur, marine salt, gypsum, and other sulphuric salts, may probably be connected with certain great submarine eruptions; but we are prevented from clearly giving the date of this formation, in consequence of the absence from it of organic remains, with the existence of which the exhalations that gave rise to the sulphureous deposits seem to have been incompatible. In this formation occurs a phenomenon, commonly, though we conceive improperly, denominated, an *air volcano*. The most noted instance is at Macaluba near Girgenti; but as we shall consider in another place how far it may be regarded as connected with volcanic agency, we shall at present omit any more particular mention of it. It may serve to convey some kind of idea of the extended period during which volcanic operations have continued in this Country, when we are told, that the whole probably of Mount Etna belongs to a period more recent than the lavas of the Val di Noto. At its foot, indeed, are several isolated rocks; as, for example, the Cyclopean rocks off the coast near Catania, that of La Motte, &c. which seem to belong to the class of submarine lavas, and may perhaps be as ancient as some of those already mentioned; but Etna itself is made up, superficially at least, of a series of beds of lava and tuff, all of which possess the characters of subaerial volcanic products.

Yet according to the joint testimony of Sir John Herschel and Captain Smyth, this mountain has an elevation of about 10,000 feet, with a circumference of 90 miles, whilst, from the descriptions given by Professor Lyell of those valleys, which display the internal constitution of the mountain, and particularly that of the Val del Bove, the whole of that portion of it, which is exposed to view, appears to consist of a succession of lava beds and of tuff, intersected by dykes of trachyte and basalt. (See pl. iv. fig. 4.)

How vast then must have been the period employed in the heaping up of so enormous a mass of volcanic products, unless, indeed, the scantiness of time was compensated by increased energy of action, and the earlier portions of the history of this volcano were marked by more frequent eruptions than the later ones.

Yet, to conclude, that during the whole of this period no deluge could have washed over the country, seems an hasty assumption, implying a more thorough acquaintance with the force of the diluvial currents, and the extent of their operation upon the strata, than we can lay claim to, and likewise overlooking the manner, in which the effects produced upon the surface of this particular mountain may afterwards have been disguised by the eruptions that succeeded. We shall therefore content ourselves with that more general statement, which seems warranted by the facts before us, namely, that all the eruptions of Mount Etna, of which we have any cognizance, took place in the air, and that consequently the earliest of them do not in all probability date from so early a period, as those of the Val di Noto, which occurred, in part, at least, under water, and are covered with neptunian deposits of the tertiary period.

Island of Sciacca.

The neighbourhood of Sicily has likewise presented us with an example of one of those events, that occur, comparatively speaking, so rarely during the limits of human experience, namely, the breaking out of a volcano apparently on a new site.

On the 18th of July, 1831, a British vessel perceived in the Mediterranean, betwixt the town of Sciacca in Sicily and the Island of Pantellaria, a high irregular column of white smoke or steam, which, upon coming near, proved to be caused by a small hillock of a dark colour, elevated a few feet above the sea, which appeared to be constantly discharging stones and dust together with vast volumes of steam.

The volcano went on increasing in bulk, till it had attained by the middle of August a circumference of 3240 feet, and a height of 107. It had a crater of 780 feet in circumference, and it consisted entirely of dark vesicular lava, with a few fragments of calcareous and other rocks, not of a volcanic nature, interspersed.

During the storms of the succeeding Winter, the loose materials of that portion of the Island, which had been elevated above the water, were gradually washed away, and no other monument of it now remains, except a dangerous shoal, with a circular patch of rock in its centre, about forty-two yards in diameter, on which there are for the most part two fathoms of water, but in one spot only nine feet.

It appears from the examinations of Hoffman, that the volcano in question lies in a line, which has been subjected to volcanic action from remote antiquity, ranging from the extinct volcanic Island of Pantellaria, by the sulphureous springs of Sciacca, to Mount Etna.

It is likewise important to remark, that, according to the observations of Captain Smyth, this volcano must have been elevated in very deep water, and that even now, in its immediate vicinity, the soundings indicate successively, ten, twenty, thirty, and forty fathoms.

Till within twenty yards, says Captain Swinburne, I got no bottom, and then eighteen fathoms water, whilst from another account it appears, that at a little distance the soundings were 100 fathoms. Lieutenant Lamert, of the French brig Armide, describes a bank extending to the North-East for a mile, which, he says, did not exist before the rising of the volcanic hill, and hence he infers, that, previously to the accumulation of the scoriæ by which its existence was manifested, the volcanic force had heaved up a portion of the bed of the Mediterranean. How far such a supposition is consistent with analogy, will be considered hereafter.

Grecian Archipelago.

If from Italy we turn to the Grecian Archipelago, the phenomena just described will be found to have been repeated, more than once, within the limits of authentic History, near the volcanic Island of Santorino.

Santorino itself (see plate vi. fig. 6) is of a semilunar form, and the horns of its crescent are nearly united, through the medium of two smaller volcanic Islands, called Therasia and Aspronesi, so that they together nearly encircle an area of above six miles in diameter, throughout a great part of which the sea is unfathomable. The beds on all these Islands dip at a slight angle towards the exterior of the group, just as would happen, if these Islands had constituted the walls of one vast crater, formed by the heaving up of the beds from the bottom of the sea, as Von Buch and Humboldt imagine to have been really the case.

Whether this be the true explanation, or not, of the position of the beds in the three principal Islands, will be considered afterwards; but a similar operation to the one supposed, although on a scale of inferior magnitude, appears to have taken place in more modern times, in the midst of the bay enclosed between the above-mentioned rocks.

Thus, 197 years before Christ, the island of Hiera, now called Palaia Kammeni, (plate vi. fig. 6,) is stated to have been thrown up from the bottom of the sea, and in the reign of Claudius, A. D. 46, another made its appearance, which in the year 726 was joined on to Hiera. In 1573, that called Little Kammeni was produced; and lastly, in 1707, New Kammeni was raised in the midst of the basin. The latter is distinctly said by the Jesuit Goree to have been heaved up from the bottom, as indeed the other Islands are reported to have been, and he alleges in proof of it, that a large quantity of fresh oysters were found adhering to the rock so thrown up.

Santorino, with its contiguous Islands, is chiefly composed of trachytic conglomerates, and tuffs covered with pumice, though in one part clay slate, and in another, according to Tournefort, granular limestone, appear.

From Santorino, a line of volcanic operations extends itself through Milo and Argentiere to the Eastern coast of the Peloponnesus, (see plate vi. fig. 5,) where before Modon (Methone in Argolis) are several rocks, called the Islands of Pelops, of a volcanic nature, and where also a promontory exists of a conical form, which appears at an early period of Greek History to have been heaved up. Ovid alludes to it in his *Metamorphoses*, and Strabo confirms, what otherwise might have been regarded as the fiction of a Poet, stating, that even in his time manifestations of volcanic agency still were observed.

Iceland.

To complete our account of those decided evidences of volcanic action, which are to be met with in Europe, we must refer to the Island of Iceland, where, from the earliest authentic records till the present day, volcanic operations have continued, on an extraordinary scale, and with intervals rarely exceeding twenty or thirty years between each. The volcanos in that Country are placed in general linearly, and the following ones are enumerated."

Hecla, the last eruption of which was in 1766.

Kattlagiaa, which, after an interval of sixty-four years, had a violent eruption in 1823.

Eyafialla Jokul, which, after intermitting for a century, had an eruption in 1821.

Grimvatn, a lake which became the site of an eruption in 1716.

Skaptaa Jokul and Skaptaa Syssel, two contiguous volcanos, experienced violent eruptions in 1783, which ravaged a vast extent of the country adjoining them.

The lava made for itself a passage into the plain at the base of the mountain, by three streams about eight miles apart one from the other. These currents of lava, reuniting, covered a space of more than 1200 square miles. The ejections of ashes which terminated this eruption continued an entire year, during which the whole atmosphere was constantly darkened by thick clouds of cinders.

Other volcanic phenomena are frequent in Iceland. In 1783, a year memorable in its annals for the violence of the eruptions that took place in it, a new Island was thrown up, consisting of high cliffs, a mile in circumference, which, however, the following day, sunk again, leaving nothing but a reef of rocks, from five to thirty fathoms under water, to indicate its former site.

Geysers.

Although we have abstained in general from noticing the hot springs that occur in volcanic districts, not only as leading us too far, but likewise as tending to introduce amongst the fundamental facts upon which we build a set of phenomena, the origin of which some may regard as problematical, yet are we induced by the obvious nature of the connection that subsists between the Geysers or hot springs of Iceland and its volcanos, as well as by the general interest which attaches to the former, to notice them amongst the effects of the same agency there exerted.

The Geysers are intermittent hot springs, which throw out at intervals a column of water, succeeded by copious volumes of steam.

The intermittent character of the phenomena may be seen explained on very simple principles by Sir George Mackenzie in his *Travels in Iceland;* and there is no doubt, but that the existence of subterranean cavities, serving as recipients for water in a heated bed of rock, and communicating with the surface by narrow orifices, would cause a generation of vapour, which occupying the upper portions of such caverns, would at intervals acquire elasticity enough to expel the water, and thus provide for itself the means of escape.

The water is strongly impregnated with silex, an ingredient almost universally present in hot springs, but in none so abundantly as in these; nor is it improbable, that the high-pressure steam which we know to be generated in this instance, may materially assist in reducing the silica to a state of solution, for it has been found, that even glass becomes quickly corroded by steam of this description, although it resists it when of ordinary elasticity.

The only other active volcano in the North of Europe is that in the Island of Jan Mayen, off the coast of Greenland. This, when visited by the Rev. Mr. Scoresby in the year 1817, exhibited all the marks of a recent eruption, and was found to consist of cellular lava, of tuff, and of scoriæ.

On the summit was a crater, no less than 500 feet in depth, and about 2000 in diameter.

Extinct Volcanos of Europe.

Having now enumerated the several sites of volcanic operations in Europe, which still continue in some part or other to exhibit marks of activity, we must next take a rapid survey of those in which the same forces have at some former period incontestably been at work, but where they seem, so far as human experience goes, to have expended themselves.

In this review we shall omit all, excepting those extinct volcanos which have operated apparently under similar circumstances to those of the present day, passing over altogether the consideration of such rocks, as, though inferred to be volcanic, differ nevertheless from the products of existing ones, in a manner which seems only explicable, by supposing an alteration in the circumstances under which they were ejected.

Portugal.

In this review, it may be convenient to begin with the most Southern portion of Europe, namely, the Spanish Peninsula, tracing up the indications of the same kind that occur until we reach Germany, above which, it may be observed, no phenomena of the kind are observable; for although in various parts of Great Britain and Ireland, in the Hebrides, the Faroe Islands, and even in the Scandinavian Peninsula, trap rocks of various kinds are extensively developed, yet these, for reasons already assigned, do not come under our present consideration, being nowhere distinctly proved to be produced, as the others have been, in the open air.

On the Eastern side of the peninsula, we meet with volcanic appearances, in the Province of Algarve, near Cape St. Vincent; and, on the road from Cintra to Maffra, near Lisbon, occur alternations of semivitreous basalt with tertiary limestone. The occurrence here of the former is worth noticing, from the formidable earthquakes with which Lisbon has more than once been visited.

Dolomieu notices also in the Province of Biera, certain volcanic appearances throughout the chain of mountains called Sierra de l'Estrella, but we are not aware, that they have been examined by any more recent observer.

Spain.

On the Eastern side of the Peninsula occur indications of volcanic action at Cape de Gaieta, near Almeira, and further North, as it is said, in the mountains above Alicant, where earthquakes are frequent and severe; but the most decided and the best established indications of the kind occur in Catalonia, near the town of Olot. No sooner have we descended the Northern declivity of the Pyrenees towards the Eastern extremity of that chain, than we meet with a volcanic district of about fifteen geographical miles from North to South, and about six from West to East, the vents of the eruption ranging linearly in the former direction, whilst the currents of lava have descended in the latter.

There are about fourteen distinct cones with craters, most of them as entire, as those in the neighbourhood of Naples, or on the flanks of Etna. They have broken through sandstone, shale, and limestone, belonging to the secondary period, but appear to be posterior to the most modern tertiary strata that exist in the neighbourhood, being covered only by the detritus of their own and the contiguous rocks. In the XVth Century the whole of the town of Olot, with the exception of a single house, was thrown down by an earthquake, accompanied, as it is said, by an eruption; but this latter circumstance is regarded by Professor Lyell as apocryphal; and there appears to be no certain record, as to any of the volcanos of this district having been in an active state during the historical period.

France.

Traces of volcanic action are found immediately North-East of the Pyrenees, in a little hill, composed of scoriæ, and possessing a regular crater, which borders on the sea near the town of Agde, between Beziers and Montpellier. Thence, a line of volcanic rocks, of various degrees of antiquity, extends into the Cevennes, and connects itself with a more extensive igneous formation in the Vivarais. (Dep. d'Ardeche.) The latter extends itself into the contiguous Department of the Haute Loire, where round the town of Puy it is most fully developed; and the same appearances are renewed in the Cantal, near St. Flour, whence they occupy a wide extent of country, until, after forming the elevated range of Mont Dor and the mountains about Clermont, they terminate Northwards near the town of Riom.

To give any thing like a particular account of the rocks comprising those extensive districts, would occupy too much space, but it may be well to state briefly the general characters, that distinguish in all of them the volcanic formations into two great classes.

There is then, in Auvergne, in the Vivarais, and even in the vicinity of Puy en Velay, an extensive group of volcanic hills, possessing craters, and having streams of lava proceeding from them, which in no respect differ, Geologically speaking, from the products of igneous action which we witness daily forming before our eyes. Though no records remain of the period in which these lava streams were ejected, still it is evident, from their shaping their course in conformity to the valleys of the district, that no great changes in the external configuration of the country can have taken place, since the period of their ejection; so that this one circumstance constitutes a broad line of distinction between these and other rocks in the same district, which have themselves been acted upon by the causes, that have excavated valleys in the contiguous formations.

It may, indeed, be true, that some of these volcanic rocks are themselves excavated to a considerable extent by the rivers which flow over their surface, as is remarkably exemplified in the Vivarais, where certain lava streams, which manifestly flowed, since the great features of the country had become as they are found at present, have nevertheless been themselves scooped out, to the depth of 70 or even 100 feet, by the action of the streams that flow at their foot.

Practically speaking, however, no one can confound the ravines, which have been channelled in lava streams of more modern date, with the valleys, by which the rivers which excavated these ravines have their course determined; so that the distinction adverted to may be admitted on the score of convenience, even by those who object to the principle on which it is founded. Whether, indeed, the valleys in question have been produced by the continued operation of the same streams, to which we refer the ravines, is a question more fitted for another part of this Treatise; but, as the majority of English Geologists, in speaking of valleys of this description, and of the detritus resulting from their excavation, still retain terms, which appear to recognise the principle of their having been produced in a different manner, designating them, as diluvial valleys, diluvial deposits, &c., so we shall adopt a similar nomenclature with reference to the volcanic products of Auvergne, speaking of those which are posterior to the valleys of the district, as postdiluvial, and those which are themselves hollowed out by valleys of the same character with the contiguous rocks, as antediluvial formations.

The postdiluvial volcanic products, then, are distinguished by the same characters, which belong to the modern lavas of Etna or Vesuvius, and may be traced to craters often preserving nearly unimpaired their original integrity. In Auvergne alone little less than seventy of them have been enumerated, which possess, in general, a great uniformity of character, and evidently all belong to an epoch, at which the adjoining country had already become dry land. In the neighbourhood of Clermont, however, are five conical hills, (see pl. iv. fig. 5,) in the midst of a group of these volcanos, possessing a striking difference in their aspect and constitution. They are composed of an earthy and pulverulent variety of trachyte, called domite, are altogether destitute of craters, but in general lie detached, in the midst of a sort of amphitheatre of volcanic hills, consisting of scoriform pyroxenic lavas.

The loftiest of these mountains, the Puy de Dome, gives its name to the Department in which it is situated; the others, the Puy de Sarcouy, the Grand and Petit Cliersou, and the Puy de Chopine, lie contiguous, but are so detached one from the other, that it would seem impossible to imagine them parts of a formation that once spread over the intervening country, even if there were not other difficulties in the way of such a supposition. It was the appearances of these rocks, that originally suggested to Von Buch, in an early stage of his career, the theory, which he has since applied to other volcanic formations in different parts of the World, with regard to the heaving up of conical masses of rock, previously softened, by the force of the elastic vapours generated by volcanic operations. The phenomena presented by one of these hills, the Puy Chopine, strongly confirm this view; as we see there an intermixture of trachyte, with granite, and other primitive rocks in various states of alteration, according, as it should seem, to the different degrees, in which they have been severally affected by the igneous action, to which their elevation is attributable. The Puy itself is situated in a sort of crater, the walls of which are composed of scoriform lavas of the ordinary description. The five domitic hills just alluded to, may, perhaps, belong to the postdiluvial class of volcanos, but at a short distance from them occurs an elevated and extensive table land, called the Mont Dor, the great mass of which consists of trachyte, of a more compact and crystalline description, and clearly of an older date. Vast masses of tuff, similar to the puzzolana near Naples, accompany it, and the whole is capped, either with basalt, as is the case at Mont Dor, or by porphyry slate, as in the neighbouring Department of Cantal, where this same formation extends itself. The whole rests upon the freshwater limestone belonging to the tertiary period, which, however, in a few places, alternates with it, and it is intersected by valleys as wide and as profound, as those which traverse any of the older rocks in the contiguous country These, therefore, we shall venture to denominate antediluvial, in order to mark the difference, both in character and in age, that exists between them and the rocks before mentioned. These last, indeed, appear from various circumstances to have been formed under water, and can, in no instance, be traced to any crater or focus of eruption; whether it was, that the changes that have subsequently taken place in the country obliterated the traces of them, or, what is more probable, that they were originally ejected through the medium of dykes, and under a pressure which confined the focus of eruption within the narrowest limits.

Be that as it may, it is certain, that the appearances presented by the volcanic rocks of Mont Dor and Cantal, are of a totally distinct character from those of Vesuvius or Etna. Instead of narrow bands of lava covered with beds of tuff or loose scoriæ, these mountains present continuous beds of trachyte, basalt, and conglomerate, mantling round the axis of the chain, and interrupted only by the valleys which intersect them. How these rocks could have been brought into their present inclined position, will be a matter for subsequent inquiry; at present, we are only concerned with the circumstances, in which the structure of these mountains differs from that of the volcanos now forming under our eyes.

The structure of the volcanic district in the Velay and Vivarais is of an analogous kind, consisting of immensely thick deposits of volcanic tuff, generally resting on a fresh-water tertiary limestone, and of rocks of trachyte and porphyry slate, which appear to be of subsequent date, and to have forced themselves through the tuff which they overhang.

The depth of the valleys, excavated in this great tufaceous deposit near the Puy, serves to evince, either the long continuance, or the energetic action of the causes which have since affected it, and the irregularly abrupt and almost pyramidal form, which belongs to some of the detached hillocks, which lie scattered over the valley, as that on which the cathedral and part of the town of Puy is built, and as the contiguous rock of St. Michael, evinces the irregular manner in which this material decomposes, and the firmness with which its parts in certain positions cohere. The last-mentioned districts also, like those of Auvergne, display many indications of volcanos possessing a more recent date, such as craters still remaining in all their original integrity, beds of scoriæ which have been ejected, as at present, in the open air, and lava streams, which have descended into the valleys in conformity with the present configuration of the country. Some of these lava streams, however, are themselves deeply channelled by the rivulets that flow across them, and being composed of compact and columnar trap, the sides of the ravine are flanked by basaltic colonnades.

Germany.

In proceeding to Germany, we may remark, that a chain of primary rocks, with many secondary formations superposed, stretches with certain interruptions through the heart of the country from East to West, of which the several portions are respectively distinguished by the names of the Thuringerwald, the Fichtelgebirge, the Erzgebirge, the Riesengebirge, &c. In connection with this great back bone, as we may term it, of Germany, and on either side of it, occur groups of volcanic cones, or other indications of an igneous character, whilst to the North of the above line they are entirely wanting.

Eyfel Volcanos.

Beginning with the Rhenish Provinces, we observe immediately at the foot of the Ardennes, in a district called the Eyfel, a cluster of little volcanic cones, composed, for the most part, of loose scoriæ, and frequently having very perfect craters, which sometimes serve as reservoirs for the waters of the country, and thus are converted into lakes; at other times are dry, and exist in all their original integrity. Accordingly, notwithstanding the silence of history concerning their eruptions, we can scarcely dispossess ourselves of the idea that they were the work of a recent period, and are persuaded, that they at least belong to as late a Geological epoch as that which we have assigned to some of the volcanos of Sicily and Naples.

They are remarkable for the general absence of any lava-currents proceeding from them, being for the most part mere aggregates of scoriæ, or a sort of volcanic tuff, made up of pulverulent materials ranged round a central aperture. They in some cases consist merely of the ordinary rocks, upheaved, but in other respects but little altered in appearance. The above, however, appear to be the only vestiges of volcanic action in Germany, that admit of being clearly referred to the same modern epoch, the other rocks, which bear marks of a similar origin, being destitute of craters, and more compact in their structure.

Siebengebirge.

On the Eastern bank of the Rhine, opposite to Bonn, rises abruptly from the borders of the river the chain of mountains, called the Siebengebirge, from the seven principal peaks that strike the eye from a distance. They are composed, partly of basalt, and partly of trachyte, which appear to have been protruded through the schists, that constitute the fundamental rocks of the district. The superposition of the volcanic products to the brown coal so extensively met with in this Province, is, however, decisive with regard to the tertiary origin of this deposit. The Siebengebirge are, in fact, a prolongation of the extensive basaltic formation of the Westerwald, which again is connected with another considerable volcanic district North East of Frankfort, called the Vogelsgebirge.

From the latter, the isolated basaltic cones of Frankfort and Hanau on the one side, and of Cassel and Eisenach on the other, seem to be ramifications. In many of these basaltic rocks, the compactness of structure is quite equal to that of the trap in older formations, but in other cases, they are associated with vesicular lavas, which occur less frequently at least, if they are not entirely absent, in the latter. The contact between the volcanic material, and the contiguous stratum, has often been productive of very striking changes in the structure of the rock, rendering, in particular, the sandstone hard and prismatic, just in the same manner as is done in some parts of this country by artificial heat.

Higher up the Rhine, occur several groups of rocks possessing a similar origin to the above. In the Odenwald, near Heidelburg, rise some eminences from the midst of the new red sandstone, in which basalt is found associated with augite rock; and near Freyburg, in the Brisgau, is the series of hills, of which that called the Kaiserstuhl is the most prominent, destitute of craters, but containing, intermixed or associated with compacter rocks, vesicular products much resembling recent lavas. Lastly, a few miles to the North of the Lake of Constance, is the commencement of another chain of basaltic and porphyritic cones, connected with which, are certain overlying masses of basalt in Wirtemberg, along the chain of the Rauhe Alp South of Tubingen. These latter, however, have more of the characters which mark the older trap rocks.

In the Rhöngebirge, a group of mountains East of Fulda, a continuation of the same volcanic formation has been noticed, though recent observers have pronounced it to be destitute of craters; and at the Fichtelgebirge, on the North-Eastern limit of Bohemia, occurs a series of basaltic cones extending from Egra to Parkstein.

The same rocks may be traced to Toeplitz in Bohemia, and to the Riesengebirge in Silesia, whilst on the lower side of this chain of mountains, which is there called the Erzgebirge, occur several platforms, cones, and domes of basalt, overlying the other rocks of the country, and therefore posterior to them all. It was these, which impressed Werner with the idea of the aqueous origin of trap, from the marked contrast he observed between the characters and position belonging to these rocks, and to the volcanic products of the present day.

Lastly, on the Western border of Moravia, near the frontier of Hungary, is a small basaltic deposit near Banow.

The above statement, it is feared, affords but an imperfect enumeration of the several sites, in which volcanic action has at former periods of the Earth's history manifested itself throughout Germany, whilst it is probable, that many of the trap rocks alluded to belong to the class, which has been in general omitted, namely, that of submarine lavas; nevertheless it may have its use, in pointing out an important fact in the natural history of volcanos, namely, the *linear* direction which they assume, and their connection with the leading chains of mountains in the country, corresponding also with the direction, in which the shocks of earthquakes are most commonly propagated, and in which hot springs occur.

Hungary.

Connected with some of the more Eastern of these groups, is a very extensive volcanic formation in the North of Hungary, consisting of five principal groups, the first of which, in the district of Schemnitz and Kremnitz, occupies an elliptical space of about twenty leagues by fifteen.

The second, a smaller group South of the preceding, forming the mountains of Dregeley, near Gran, on the Danube.

The third, a mountain group known by the name of Matra, situated in the heart of Hungary, East of the former.

The fourth, a chain which commences at Tokai, and extends North to the heights of Eperies, in length twenty-eight or thirty leagues, and in breadth about five or six.

The fifth is that of Vihorlet, East of the foregoing group, which is connected with the trachytic mountains of Marmarosch on the borders of Transylvania.

The latter form a wide range extending from Vasarhely near the Western declivity of the Carpathians along the line of the river Marosch, nearly to Cronstadt on the frontiers of Walachia.

Now it is remarkable, that throughout the whole of this tract, studded as it is with indications of volcanic agency, no evidences of a continuance of the same has been discovered, unless the Solfatara of Budoshegy in Transylvania be regarded in that light. Neither do any craters exist, except at the Southern extremity of this latter chain, and perhaps near the Lake of Balaton in Hungary.

In other situations, the prevailing rock is trachyte, which occurs in a state of greater developement, and consequently under a greater variety of aspects, than any where else in Europe. This is associated with pumice and other cellular products, which indicate that it was not formed under deep water; an inference confirmed by observing, in the pumiceous conglomerates derived from the trachyte itself, shells of the same age as those met with in the basin of Paris. (Beudant.) It would seem then, that the volcanic eruptions of Hungary took place at a period, when the low country was overspread with extensive fresh-water lakes, of which that of Balaton, near which locality they appear to have continued longer than elsewhere, is the only considerable remnant.

In Styria also, a little to the South east of Gratz, occurs a series of volcanic hills, grouped round a central trachytic eminence, the Gleichenburg. (See pl. v. fig. 10. for an ideal section of the arrangement of the strata round the central trachyte in that Country.) And it is probable that others exist in many parts of Turkey.

It is certain that on either side of the Sea of Marmora, from the Dardanelles upwards to Constantinople, occur volcanic rocks, whose porous and vitrified aspect announces a modern origin, but they appear to be destitute of craters.

On the Volcanos of Asia.

Asia Minor.

With the line of extinct volcanos on the shores of the Bosphorus is probably connected that which has been described by Mr. Webb as existing in the Troad, and which is developed still more extensively in the neighbourhood of Smyrna. The latter district was called, according to Strabo, the Catacecaumene, from its burnt and arid appearance, nor does this ancient Geographer hesitate, to refer the characters it bears, to the action of fire proceeding from the earth. (*απο γηγενους πυρος.*) He also speaks of a Plutonium or cave exhaling carbonic acid, which still appears to exist in this neighbourhood, a proof of the long continuance of processes resulting from this deep seated cause.

Dead Sea.

In Syria, and especially in the neighbourhood of the Dead Sea, occur indications of volcanic action, belonging apparently to a still more recent date; at least, if we are justified in supposing the awful event, relative to the destruction of the cities of the Pentapolis, recorded in the Book of Genesis, of which the Dead Sea is stated as the result, to have been brought about by the immediate operation of volcanic forces.

The exact mode, in which it came to pass, that the River Jordan, which appears at one time to have flowed into the Red Sea, (see pl. vi. fig. 1.) created that expanse of waters which now occupies the valley of the Pentapolis, and in which the stream at present loses itself, must of course continue a matter of surmise, until some adventurous traveller shall have examined the country South of the Dead Sea with Geological eyes. It may, however, be suggested, that if one of those volcanos which, we are told, exist South of the Dead Sea, had given rise to a current of lava of considerable thickness, which took possession of the bed of the river, the waters of so considerable a stream, confined within the compass of the valley, would have spread themselves over it, until they had converted what was before a fertile plain into a wide waste of waters.

Such a supposition is at least agreeable to analogy, for Auvergne alone supplies us with more than one instance of a lake being produced, owing to the ponding up of the waters of a river by a stream of lava; nor ought it to be objected to as inconsistent with the authority of Scripture, which in this, as in other instances, only informs us, with regard to the reality of the event, and the moral end it was intended to answer, without seeking to enlighten us relative to the physical means by which it was brought about.

Dr. Clarke and other travellers notice similar volcanic appearances in Palestine; and some of the sacred Prophets, from certain allusions that occur in their writings, appear to have been eye-witnesses of, or at least familiarly acquainted with, volcanic phenomena.

Red Sea.

The existence of extinct volcanos at Sherm in the Peninsula of Mount Sinai, may enable us to connect the phenomena exhibited in Palestine with the active volcano of the Island of Zibbel Teir in the Red Sea, and with other appearances of the same kind that have been noticed in Arabia.

Central Asia.

There is reason also to believe, that volcanic operations may be traced along a line, where we should be least disposed to anticipate their occurrence; namely, across the centre of the great Asiatic Continent. To the West and South of the Caspian lies the chain of the Caucasus, which presents in many parts indications of the kind. Mount Ararat itself is stated to be an extinct volcano, and some mountains further North, near the River Kuban, are stated to be composed of materials similar to those of the trachytic hills near Bonn. Demavend, the highest peak in the chain of Elburs, itself a branch of the Caucasus, is an extinct, if it be not now an active, volcano, for it is reputed sometimes to emit smoke, and Morier mentions traces of the action of fire South of this point, between Teheran and Ispahan.

If we cast our eye on the mass of Central Asia, we may observe a series of lakes or seas, of which the Caspian is the most Eastern, extending far into the Chinese territory. These lakes are indications of a great depression of the Earth's surface, which Humboldt conjectures to extend Northward to the Frozen Sea, at the mouth of the River Ob, on the Eastern side of the Oural mountains, and which stretches Eastwards between the two nearly parallel ranges, the Altai and the Teen-shan or Celestial mountains. This depression is not merely a relative, but an absolute one, for Engelhardt and Parrot have ascertained by barometrical measurement (and the same has been confirmed in a very remarkable manner, by the observations made on the boiling point of water by a recent English traveller Captain Monteith) that the Caspian, which occupies its present level, is below the surface of the Ocean; and the existence of salt in the soil as well as in the lakes, together with the presence of sea-shells identical with existing species, indicate, that at no very remote era, Geologically speaking, a large portion at least of this tract was occupied by water, of which the Caspian, the Lakes of Aral, Baikal, &c. are the residue.

Now it is in this depressed portion of the great Asiatic Continent, that the volcanos, which are reputed to exist in Central Tartary, have broken out.

The extinct volcano of Aral Toobe, which is an Island in the Lake of Alakul, and the Solfatara, as Remusat calls it, or the active volcano, as Humboldt is inclined to consider it, of Peechan or the White Mountain, both lie on the Northern declivity of the Celestial Mountains, the latter not very distant from the Lake of Issikoul, which appears to be about double the size of that of Geneva. It had an eruption in the VIIth Century. In its neighbourhood is a mountain called Ourumski, five leagues in circumference, which produces immense quantities of sal-ammoniac, and which probably is the crater of a Solfatara, or half-extinguished volcano. Near the Lake of Darlai also is a small mountain full of fissures rising out of a plain adjoining the banks of the River Kobok, in which the same salt sublimes.

Eastward of Pechan, the whole Northern slope of the Celestial Mountains presents volcanic phenomena, for lava and pumice abound, and various exhalations are here and there emitted.

Southward of the same chain also occurs the volcano of Tourfan, in latitude 43° 34′, called Ho-Tcheou, town of fire; though it seems doubtful, whether this be in an active condition at present. It is said to be in the midst of several considerable, though, according to Humboldt, shallow lakes, and produces large quantities of sal-ammoniac. Thus Humboldt concludes, that we are acquainted with a volcanic territory in the interior of Asia, the surface of which is upwards of 2500 square leagues, and which is distant 300 or 400 leagues from the sea; a remarkable exception certainly to the general fact of the propinquity of volcanos to the Ocean, though one not more extraordinary, perhaps, than the position of Jorullo in the centre of Mexico, seeing that all these volcanos, in consequence of their mutual connection, may be supposed to communicate with the lakes, that occur in the longitudinal valley in which they are situated, just as the Mexican volcano, by its connection with the other vents which stretch across the American Continent, appears to be with either Ocean.

Kamtschatka.

The exact condition, however, in which the volcanos of Central Tartary now continue, must, after all, be open to some uncertainty, seeing they have never yet been examined by any European traveller; and the only ones, whose existence on the Continent of Asia can be looked upon as ascertained, are those in the Peninsula of Kamtschatka, where three in a very active condition are enumerated

Thence we may, to all appearance, trace a chain of volcanic operations along the Aleutian Islands to the Peninsula of Alaschka, in North America, where indications of the kind are said to occur.

Among the Aleutian group, Langdorf has described a rock near the Island of Unalaschka, 3000 feet in height, consisting of trachyte, which made its appearance at once from the bottom of the sea in the year 1795, an occurrence, which may serve to render more credible the traditions which have reached us, as to the rise of new Islands elsewhere in the sea.

The volcanos of Kamtschatka are connected again with a very extensive range of similarly formed mountains in Japan, through the medium of those of the Kurule Islands, in which no less than nine active vents are enumerated.

Indian Archipelago.

Other links in the same extended chain of igneous operations may be observed in the Islands of Loo-Choo, probably in that of Formosa, and in others connecting Japan with the Philippine group. (See pl. vi. fig. 4.)

Luçon, the largest of these, contains three active volcanos, one of which, that of Taal, South of Manilla, had an eruption in 1754. The Islands of Fugo and Magindanao likewise contain each a burning mountain. The line is thence prolonged through Sanguir and the North-east extremity of Celebes, by Ternate and Fidore to the Moluccas. In Sambawa, belonging to this latter group, one of the most formidable eruptions ever known has been recorded by Sir Stamford Raffles, the effects of which were felt over a space of 300 miles, extending itself through the whole of the Molucca Islands, Java, &c.

From Sambawa a great transverse line of volcanic operations may be traced from East to West. On the West it passes through Java, then bending Northwards is prolonged through Sumatra, and terminates in Barren Island, in the Bay of Bengal, about the 12th degree of North latitude. (See pl. iv. fig. 4.) To the East of Sambawa the volcanic range extends itself to Banda and New Guinea, and then expands over the greater part of the Pacific Ocean, which appears to constitute but one great theatre of volcanic operations.

Pacific Ocean.

The Islands dispersed over this vast expanse may indeed be referred to two classes; those of low elevation, which appear to consist entirely of coral reefs, and those of more considerable height, chiefly consisting of volcanic peaks. But even the former appear to be in the great majority of instances based upon submarine volcanos; for it seems to be ascertained, that madrepores will not commence their building operations at a depth greater than about twenty feet below the surface of water; and where the subjacent stratum has been explored, a rock of volcanic nature has in general been detected as its basis. Among the loftier Islands of the Pacific Ocean occur some of the most remarkable volcanos of the Globe, especially that of Kirauca in the Island of Owhyhee, described by Mr. Ellis, which appears to be in a state of incessant activity, and Mouna-roa, an extinct one, the height of which is calculated at 16,020 feet.

Other volcanos are stated to occur in different parts of that extensive tract, as far as New Caledonia and New Hebrides. The separate mass of New Zealand, with which Norfolk Island is connected, may be viewed as the Northern extremity of the bulwark; its Eastern can hardly be fixed at any nearer point than the coast of America, since it appears, that an active volcano at present exists among the Galapagos only 10 degrees West of Quito.

On the Volcanos of Africa.

Nor are volcanic phenomena limited to those Islands only which lie Eastward of the Indian Archipelago; for we have reason to believe, that a large proportion of those which may be regarded as dependences upon the Continent of Africa, are derived in great measure from the same cause.

How, indeed, the case may stand with regard to the largest of them, Madagascar, our imperfect acquaintance with that extensive tract affords us but few data for determining; though Ebel (Bau der Erde) states the existence there of a volcano, and some specimens that were sent from thence to the Geological Society seem to corroborate his statement.

We know, however, that the smaller Islands in its vicinity, namely, the Mauritius and the Isle of Bourbon, are made up entirely either of volcanic materials, or of the coralline limestone of modern growth. In the centre of both these Islands rises a conical mountain, constituting the most elevated point of each; but in the Mauritius there is no semblance of volcanic action at present, whereas, in the Isle of Bourbon exists one of the most active vents in the World; for since 1785, the year in which a register of its eruptions was commenced, up to 1801, at least two lava streams annually have been thrown out from the sides of the mountain, and of these, eight have reached the shores of the sea. These currents of lava from the lower part of the mountain are followed by ejections from the craters situated on its summit, and amongst the substances thrown out is that filamentous variety of pumice, which so resembles spun glass in appearance and flexibility.

These lavas are of a trachytic character, but the Island itself is principally composed of beds of compact and amygdaloidal basalt, alternating with tuffs, the whole being intersected by basaltic dykes.

Besides this active volcano, an extinct one of larger size, called Les Fournaises, exists in the West of the Island. On the Continent of Africa itself, we have no well-ascertained instance of volcanic agency, though the German traveller Rüppell reports, that in Kurdofan, 150 leagues from the Red Sea, and, consequently, far in the interior, a conical and smoking mountain was stated to him as existing.

We will proceed, therefore, to the Islands on the Western side of Africa, beginning with St. Helena, which appears to be made up of coralline limestone and volcanic matter, the disposition of the latter being towards the centre of the Island, where a crater shaped cavity exists.

The Island of Ascension, of Tristan d'Acunha, and that called Gough's Island, are also volcanic, and so likewise are those of Fernando Po and Prince's Island, in the Bight of Biafra.

The Cape Verd Islands are composed chiefly of tertiary limestones and volcanic products, but no active volcano exists amongst them, except in the Island of Fuego, which is reported to be in a state of constant activity.

Canary Islands.

Ferro, the next in the series, is volcanic, and a burning mountain burst out in it in 1677, which again, in 1692, caused an eruption of six weeks' duration.

Indeed, the whole group of the Canaries seems to be placed within the sphere of the same submarine volcano; for although vestiges of other rocks are met with, as of granite and mica slate in Gomera, and of limestone in Great Canary, Fortaventura, and Lanzerote, yet none of these Islands are exempt from occasional manifestations of the same igneous action.

Teneriffe.

In the Island of Teneriffe we see exemplified, almost every variety of volcanic product that elsewhere exists.

The Peak, a conical mountain which rises to the height of about 12,000 feet, is itself composed of trachyte, but it rises out from the midst of rocks, consisting of basalt and the compacter forms of pyroxenic lavas.

The crater of the Peak has given rise to ejections of vitreous lavas, partaking of the character of obsidian, together with loose masses of this substance and of pumice.

At present, however, the principal eruptions take place from the flanks of the mountain, and at a much lower level, namely, from the parasitic cone of the mountain Chahorra, which bears the same relation to the Peak, that the Monte Rosso does to Etna; and it is remarkable, that pumice never has been thrown out by any of these later paroxysms, the products of which are lavas or loose masses, possessing a stony aspect, a black colour, and a large proportion of pyroxene; substances, in short, bearing the same relation to the compact traps constituting the basis of the mountain, which the trachytes do to the clay porphyries found amongst older rocks.

The remainder of the group, as described by Von Buch, appears to consist of submarine lavas similar to those which constitute the base of Teneriffe; in the Islands of Great Canary, of Palma, and others, the beds composing them rise in all directions upwards towards the centre of the Island, where occurs a circular cavity, called a Caldera, similar in shape to a crater, but destitute of lava currents, more profound and abrupt, and of greater circumference.

The Caldera in the Isle of Palma is 5000 feet in depth, and about two leagues in diameter, and from its summit, the edges of the beds, of which the Island is composed, are seen in regular succession, intersected by a network of basaltic dykes.

Another prominent feature in these Islands, is the occurrence of deep and abrupt valleys called Barancos, which intersect the strata, radiating in all directions from the centre to the circumference. Their precipitous escarpments, and the absence of any streams running through them, plainly denote that they owe their origin, not to water, but to something connected with the peculiar physical structure of the Island; and Von Buch observes, that both the position of the rocks themselves and the barancos with which they are intersected, admit of a simple explanation, if we suppose a succession of submarine lava-beds to have been upheaved by the action of elastic vapours from the bottom of the sea, the Caldera, towards which all the strata rise, being the point that first yielded to the force applied, the Barancos, a natural consequence of the splitting, which would be caused by the increase of surface over which the rocks were spread, when raised up from their original horizontal position at the bottom of the sea.

As this mode of explanation has, however, been lately disputed, we shall defer the consideration of it to a later portion of this Treatise, and shall, therefore, only remark that the Caldera of Vandama, in the Island of Great Canary, is composed principally of trachyte, (see Von Buch, p. 261.) and therefore could not have been built up by a number of successive eruptions, as has been the case with some craters. (See pl. iv. fig. 3.)

The Island of Lancerote is somewhat differently formed from the rest, presenting a series of not less than twelve little volcanic cones, three or four hundred feet in height, composed of harsh, porous, sharp lapilli, provided each with a crater, lying exactly in a line, as if they had been thrown up from a large fissure or rent extending across the Island, which had a communication with the interior.

Lancerote has been visited with several formidable eruptions, especially one which continued at intervals from 1730 to 1736, so severe as to drive away the inhabitants entirely; and another in 1824, in which a new volcanic mountain was formed by the stones ejected.

Madeira is composed in great measure of the same materials as the foregoing Islands, but no vestiges of any recent volcanic operations are discoverable; and the same remark applies to Porto Santo, which consists of an alternation of the above rocks with tertiary limestones, and sandstones disposed horizontally.

Mount Atlas.

Certain parts of Mount Atlas on the Continent of Africa, opposite to the Islands just alluded to, are said likewise to be volcanic.

The mountain called Black Harusch consists, according to Humboldt, of basaltic rocks of a grotesque form. Its Western range, called the Mountain of Soudan, has been explored by Ritchie, who describes it as formed by masses of basalt, which have burst through tertiary limestone containing fossil fish, as in the Vicentin. It was the Mons Ater of Pliny, and if any reliance is placed on the accounts of volcanic appearances reported to have been seen by Hanno whilst circumnavigating that part of Africa, it is more likely, that he should have referred to these mountains, than to the volcanos of Teneriffe, which were too distant from the coast for him to have touched upon.

Azores.

The last group of Islands in any degree connected with this portion of the Globe is that of the Azores, and this also is altogether of a volcanic nature. The Island of St. Michael, the largest of them, contains several conical hills of trachyte, some of them with craters, and covered by the pumice and obsidian they had ejected. This trachyte has, however, been protruded through strata of basalt and tuff, which constitute the fundamental rocks.

El Pico, the summit of which is 9000 feet above the sea, consists of a conical mass of trachyte, from which smoke is constantly issuing. In 1812, an eruption took place from the Island of St. George contiguous, which was probably connected with this same volcano, considered the only active one in the whole group.

In 1811 a phenomenon occurred near this group of Islands, similar to that already described as having taken place near Sicily, and in the Grecian Archipelago.

After a succession of earthquakes, experienced more or less sensibly in all the neighbouring parts, a new Island rose in the midst of the sea, of a conical form, and with a crater on its summit, from which flame and smoke continually issued. The Island, when visited soon after its appearance by the crew of the British frigate Sabrina, was about a mile in circumference, and 200 or 300 feet above the level of the Ocean.

Like the Island of Sciacca, however, it sunk again into the sea, after continuing to be visible above the waters for some weeks.

On the Volcanos of America.

Antilles.

All the smaller Islands constituting the West-Indian Archipelago, are composed either of coralline limestone of very recent formation, or of volcanic materials.

Those which consist wholly of the former, are of extremely low elevation, whilst the volcanic Islands rise often to a considerable height. The latter group may be divided into those which are entirely volcanic, and those which contain an intermixture of calcareous rocks.

The first of these classes comprises the following.

1. Grenada, in which there is an extinct crater filled with water.
2. St. Vincent, the site of an active volcano called *Le Souffrier*, which had a tremendous eruption in 1812.
3. St. Lucia, which also contains a very active volcano.
4. Dominica, the site of an extinct volcano.
5. Montserrat, of a solfatara.
6. Nevis, of the same.
7. St. Christopher's, of ditto.
8. St. Eustachia, of an extinct volcano.

The second division would comprehend,

1. Martinique, which consists chiefly of felspathic lava, constituting its three peaks, but which has calcareous rocks resting upon these volcanic materials.
2. Guadaloupe, one portion of which consists of coralline limestone, the other of volcanic rocks, containing fourteen craters, one of which is in an active condition, and had an eruption in 1797.
3. Antigua, in which calcareous rocks of recent origin predominate.
4. St. Barthelemi.
5. St. Martin.
6. St. Thomas, of which we possess no precise information.

It may be observed, that all those Islands which exhibit traces of the recent action of fire, are situated in a line on the Western boundary of the range, from North latitude 12° to 18°, and West longitude 61° to 63°.

Whatever indications of the kind occur further to the West, belong to eruptions of an older date.

Thus the volcanic islands of the Antilles seem to be the links, which connect the chain of primary mountains in the Caraccas, with that which runs across the Islands of Porto Rico, St. Domingo, Jamaica, and Cuba, both which lie nearly at right angles to that of the volcanic Islands enumerated. Yet the connection between the two is evinced, from the earthquakes, to which the non-volcanic chains above mentioned are so subject, ceasing, upon the breaking out of an eruption in one of the volcanos of the neighbouring Islands.

On the Continent of North America we meet with no recent volcanos further North than California, where three are stated as being at present in activity, although little is actually known concerning them.

Mexico.

In Mexico, traces of volcanic action belonging to every Age are strikingly manifest. Basaltic rocks and other modifications of pyroxenic lavas are met with in abundance, but the most elevated parts are composed of trachyte, which appears to have burst through the primary rocks, constituting conical or pointed mountains of enormous height. There would even seem to be a passage from these into granite, through the medium of a species of porphyry, which, though it partakes of the same ingredients as trachyte, is of a compacter texture, and which seems at the same time to be interstratified with the primitive rocks of the country.

But Mexico also presents a chain of active or half-extinguished volcanos, ranging in a linear direction across the Continent, and consequently at right angles to the primary chain above mentioned, which runs North and South.

In the parallel of the City of Mexico occur no less than five burning mountains, placed so much in the same line, that they appear to be derived from a fissure traversing Mexico from West to East; and it is interesting to remark, that if the same parallel line which connects these volcanos be extended in a Western direction, it would traverse the group in the Pacific called the Isles of Rivillagigedo, which there is reason to believe are also volcanic. See plate vi. fig. 3.

The most Eastern of these, that of Tuxtla, is situated a few miles to the North-West of Vera Cruz. In the same Province, but further to the West, occur the volcano of Orizaba, the height of which is 17,300 feet, and the peak of Popocatepetl 300 feet higher, the loftiest eminence in New Spain; whilst on the West of the City of Mexico are the two remaining ones, Colima and Jorullo. The elevation of the former is about 9000 feet. That of the latter much less considerable. It is remarkable, however, as affording us an instance of the breaking out of a volcano in a new spot; for the origin of this mountain dates no further back than the year 1759, when it was suddenly thrown up, with five smaller conical masses, from the midst of the plain called the Malpays, which also, over an area of three or four square miles, was upheaved with an inclination increasing from the circumference to the centre, the former being only thirty-nine feet above the old level, the latter no less than 524 feet. (See plate iv. fig. 1 and 2.)

Thousands of small cones from six to one hundred feet in height, called by the Indians Hornitos, or Ovens, are scattered over this upraised plain; they consist of clay intermixed with decomposed basalt, and are continually giving out steam.

Jorullo, at the time Humboldt visited it, was still emitting smoke, and had thrown out from its North side an immense quantity of scoriform and basaltic lavas. The surface of the Malpays was also still hot, and two streams of water, which were swallowed up in the hollow caused by the upheaved strata, reappeared on the other side of the plain, as warm springs.

In this brief account of the curious and instructive phenomena of Jorullo, we have taken for our guide, Humboldt, as the only scientific traveller who has given us an account of it, after an actual inspection of the spot. We are aware, indeed, that doubts have been thrown upon his explanation by certain English Geologists, who are reluctant to admit the fact, of upheavings having taken place amongst volcanic materials; but without entering into this question at present, we may remark, that those who admit the uplifting of a whole Island at once from the bed of the Ocean, (and who, that is conversant with volcanic phenomena, can question that such events have occurred?) need feel no difficulty in admitting the testimony of the Indians, or the opinion of Humboldt, with respect to the fact of a mountain like Jorullo having been uplifted bodily from the interior of the Earth.

The active volcanos above enumerated are connected, one with the other, by several which are extinct; thus between Orizaba and Popocatepetl, lies the Coffie de Perote, and between Popocatepetl and Jorullo, the extinct volcano of Mexico, otherwise called Iztaccihuatl, whilst Colima, as we have seen, lies between Jorullo and the Islands of Rivillagigedo above noticed as volcanic.

In the new Republics of Guatimala and Nicaragua, a line of volcanos occurs lying parallel, instead of transversely, to the chain of the Cordilleras. Between North latitude 10° and 15°, twenty-one active vents are enumerated. South of the Isthmus of Darien, in the Republic of Columbia, no less than thirteen occur.

One of these, the Peak of Tolima, is in the department of Cundinamarca, and the Province of Bogota, forty leagues from the coast, and amongst the central Andes. Seven are in the department of Cauca, which extends along the coast of the Pacific; four of them belong to the group of Popayan, and three to that of Pastos, two Provinces comprehended in that department; whilst further South, in the Province of Pichinca, or Quito, belonging to the department of the Equator, are five active volcanos.

The connection between these last, and the volcanos of the department first mentioned, was evinced in 1797 by the following circumstance.

A dense column of smoke had for some months been observed to issue from the volcano of Pasto in the latter Province, which all at once disappeared; and it was afterwards found, that at this exact time the town of Riobomba, sixty-five leagues further South in the Province of Pichinca, which lay contiguous to the volcano of Tunguragua, was destroyed by a fearful earthquake.

It is remarkable that the whole of this line of volcanos lies Westward of the Andes. To the East of this chain exist, indeed, three small vents near the sources of the River Caqueto, Napo, and Morena; but these, according to Humboldt, probably result from the lateral action of those of Popayan and Pasto, whilst Buenos Ayres, Brazil, Guayana, and Venezuela are altogether destitute of these phenomena.

South America.

On the Western side of the Cordilleras, however, the line of volcanic operations would seem to extend uninterruptedly along the whole coast to Chili; for although in the interval of 30 degrees that occurs between the latter Republic and Quito only one burning mountain exists, that of Arequipa in Peru, yet it seems probable, from the frequent earthquakes that agitate the intermediate tract, that the same processes are going on beneath, although no permanent vent exist for the discharge of elastic vapours.

In Chili, sixteen active volcanos are enumerated, of which two only exist on the coast, the rest being situated in the midst of the range of mountains, which runs in a direction nearly parallel to it, but further inland. Thus we may trace a line of volcanic operations along the greater part at least of the Western coast of South America, the loftiest eminences being of trachyte, which encircles in zones a large portion of the table land, but rarely extends into the valleys, forming conical mountains, which often serve as vents for the aeriform or solid materials elaborated below, but at other times are unaccompanied with lava streams or scoriæ, and apparently have no vestige of any crater.

The latter appears to be the case with Chimborazo, the highest point of the New World, whilst Cotopaxi, the next in point of elevation, has given birth to frequent and violent eruptions

SECTION 2.

Other Phenomena referable to volcanic action.

We have now completed our proposed sketch of the distribution of those volcanos, which either are in activity at the present time, or, if dormant, have at least left such evident traces of their former existence, in the rocks which they have ejected, or the lava currents which they have poured forth, that we cannot hesitate in regarding their operations, as being of the same nature, and brought about under the same external circumstances, as those of which we are eye-witnesses.

Wide indeed as may be the interval, in an historical sense, between certain of these, as, for instance, between the latest eruption even of the volcanos of Auvergne, and the earliest recorded one of Vesuvius; yet the whole together constitutes the same Geological epoch, one in which the general features of the country were nearly as at present, the climate not materially different, and the races of animals those which are now existing.

And although the earlier volcanic rocks, found in these Countries, were produced at a period to which these remarks do not apply, one in which large fresh-water, and in some instances salt-water, lakes occupied what is now dry land, when the climate was warmer, and the animals in many cases such as now no longer live in any part of the Globe; yet are these so connected in character and position with the more modern products of volcanos alluded to, that we need not hesitate, either to refer them to the same cause, or to comprehend them in our enumeration.

The case of the trap rocks is somewhat different; for though few at present contend that they are of aqueous origin, all must admit, that if produced by volcanic action, it has been by operations differing in some respects from those at present taking place, either in their own nature, or in the external circumstances which influenced them; so that in laying the foundation for a series of deductions with respect to the nature and effects of subterranean fire, where it may be best to throw aside every thing of an hypothetical character, and to consider only that which is incontestably volcanic, we should do wrong in taking into the account these igneous productions of an earlier Age.

Nevertheless there are certain other phenomena which must be contemplated, if we wish to estimate the amount of volcanic action in all its different phases.

Earthquakes.

The first of these is earthquakes, which may be proved on tolerably secure grounds to have, in all cases, a connection more or less intimate with volcanic agency, and ought therefore to be regarded as one of the modes, in which these forces manifest their existence over the Earth's surface at the present day.

In some instances, indeed, earthquakes have occurred so immediately antecedent upon volcanic eruptions, and are so manifestly derived from the same centre of action, that no better proof could be offered to establish an identity of origin.

In other cases, the evidence, though not quite so direct, is perhaps as cogent as need be required, in order to substantiate the point in question. When, for instance, we observe two volcanic districts, both subject to earthquakes, which are ascertained, by their coincidence in time and other circumstances, to have a connection with the volcanic action there going on, and find that an intermediate country, in which there are no traces of the operation of fire, is agitated by subterraneous convulsions, similar in kind, but stronger in degree, than those occurring in the immediate vicinity of the volcanos; have we not reason to conclude, that the same action extends throughout the whole of the above area, and that it is this which produces in the intermediate space the effects alluded to, which are often the more violent from the absence of any natural outlet, whence the elastic vapours set in motion, which immediately suggest themselves to us as the cause of the convulsions experienced, could find a channel of escape?

Now, in proof of the former of these positions, it may be scarcely necessary to do more than to appeal to the case of Etna and Vesuvius, which rarely return to a state of activity after an interval of repose, without some antecedent earthquake, the latter usually ceasing, so soon as the volcano has once established for itself a vent, whereby these elastic vapours can discharge themselves. Such was the case before the celebrated eruption of A. D. 79, in Campania, as well as in that of Etna in 1537, when, says Fazzello, noises were heard and shocks experienced over the most distant parts of Sicily. In such cases, no one would pretend to doubt the connection between the volcano and the earthquake.

The second point seems established, by considering the tremendous earthquakes which ravage so often Campania, and those mentioned by Humboldt as intervening between and in the line of the volcanos, of Columbia, Quito, and Chili. Von Buch has shown, in his paper on Lanzerote, the comparative immunity enjoyed by Teneriffe from those convulsions of Nature, which agitate the neighbouring Islands, destitute of that great chimney or safety-valve afforded it by the Peak of Teyde.

But before we are entitled to appeal to earthquakes, as affording an independent source of evidence with respect to the existence of volcanic action, it will be necessary to show, that no other natural cause is likely to have produced such effects, more especially as even those who admit their volcanic origin in the above cases, have, nevertheless, been disposed to assign to them a different origin in others. Such a distinction seems to be hinted at by Werner, who acknowledged two classes of earthquakes: the first connected with a particular volcano, and felt only within a radius of some miles from it, and at a period when the latter was in a state of activity; the latter less manifestly related to any such cause, being spread over a much larger tract of country, and, therefore, as he conceived, situated at a much greater depth.

Their Phenomena.

This renders it necessary for us to pass in review the phenomena most commonly attendant upon earthquakes, in order to ascertain, how far they appear to countenance the supposition, that other causes, besides those of a volcanic nature, might have contributed to produce them.

It would greatly confirm such an opinion, if it could be shown, that there were any phenomena common in one class of volcanos, which were absent from, or uncommon in, the other; but as no one has attempted to make such a distinction, all that remains to be done is to consider generally the concomitants or sequelæ of earthquakes, with a view of ascertaining, how far they are reconcilable to any other than a volcanic cause.

None of these, indeed, can be considered as universal: thus in some earthquakes the shock consists in an horizontal wavy motion; in others in an upward heaving; and in a third class in a vibration backwards and forwards.

There is usually a sort of subterranean noise attending them, which has been compared to thunder, or the rolling of artillery, but this is not constantly present; and on the other hand the noise has been heard without any concomitant earthquake. A peculiar smell of a sulphureous nature has been occasionally experienced, and other phenomena, such as the bursting out of flames from the earth, the overflowing of wells, the ejection of water from fissures formed at the time, are noted in particular cases.

The following may be enumerated as the meteorological phenomena usually coincident with earthquakes.

Irregularities in the season preceding or following the shocks, sudden gusts of wind interrupted by dead calms, violent rains at period, where such phenomena are unusual or unknown in the country; a reddening of the Sun's disk, and a haziness in the air often continued for months; an evolution of electric matter from the ground, together with indications of some extraordinary condition of the atmosphere, evinced both by the inferior animals and by man, the former uttering cries of distress, and evincing extraordinary alarm, the latter experiencing a sensation like sea-sickness or dizziness in the head. These phenomena, however, appear to be equally common during the continuance of volcanic eruptions, as of earthquakes, and indicate in both cases the tendency of any great subterranean movement, proceeding from whatever cause, to disturb the equilibrium of the atmosphere.

The only other hypotheses, by which earthquakes have been accounted for, are, that of Stukeley, who refers them to subterranean discharges of electricity, and that of Buffon, who attributes them to the falling in of caverns existing in the interior of the Globe.

The arguments that have been from time to time advanced in favour of the electrical theory are vague and inconclusive; they are drawn from some fanciful analogies between the noise and shock accompanying lightning, and those which are experienced during an earthquake; from the extreme rapidity with which the motion is propagated, to which the passage of electricity alone is comparable; from the electrical state of the atmosphere both before and after an earthquake; and from the sulphureous smell sometimes perceived, which is thought to resemble that produced by the electrical spark.

No one, however, has yet attempted to show, that any of the above phenomena are limited to those earthquakes which they are disposed to *separate* from volcanos, neither do they appear by any means incompatible with this view of their nature and origin.

Electrical phenomena are indeed equally common during the continuance of volcanic eruptions, produced in all probability by the evolution of large quantities of steam and other elastic fluids, the decomposition and subsequent regeneration of water, and other processes which accompany these great operations of Nature.

The late discoveries, indeed, which have been made with regard to the opposite electrical condition of mineral veins and the rocks containing them, may lead us to believe, that much remains to be learned with regard to the agency of this mysterious power in the interior of the Earth; yet we can hardly believe, that in the solid strata of the Globe, consisting, as they do, of conductors, the same accumulation of electricity can ever occur, as that which produces the phenomena of thunder and lightning in the atmosphere.

With regard to the theory of Buffon, it may be sufficient to observe, that the existence of cavities in rocks can only be supposed to arise from two causes; something connected, either with their original formation, as in the case of limestones, or with the convulsions that have subsequently affected them.

Now with regard to the *first*, it is highly improbable, that any great spontaneous sinking of hollows, that have existed for so long a period, should take place in the present day; and with respect to the second, the very existence of *such* hollows implies the previous exertion of volcanic agency, for we know of no other cause in nature, competent to heave up rocks in the manner necessary to produce such cavities.

Besides, although the sudden falling in of a cavity might produce a shock extending over a considerable area, yet there is no reason, why it should spread in one direction more than in another.

In truth, however, the chief difficulty, which prevented our predecessors from acting in this instance on the sound maxim in philosophy, of not assuming more causes for natural effects than were necessary for explaining the phenomena, has been removed by the progress of modern discovery, which, by increasing our knowledge of volcanos, has convinced us, that whilst their manifest distribution is far more extended than we had once supposed, the probable indications of their former agency are to be met with, in almost every part of the Globe where earthquakes have been experienced.

This, of course, renders it more easy to refer earthquakes in general to some focus or other of volcanic operations; especially if we assume, what in itself is highly probable, that the eruptions of burning mountains are only the extreme manifestations of a cause generally diffused throughout Nature, and that the minor indications of the same may therefore be looked for, where these mightier ones are unknown.

It has, indeed, been sometimes alleged, that from the wide extent over which the shock of an earthquake is sometimes diffused, the immediate seat of the action must be at a depth incalculably greater, than that which we are disposed to assign, either to volcanos, or any other natural force; and Dr. Stukeley has undertaken to overthrow the volcanic hypothesis by a sort of *reductio ad absurdum* derived from a calculation of this kind; showing, that as the earthquake which occurred in Asia Minor in A. D. 17 extended over a diameter of 300 miles, it must have proceeded from a point 200 miles beneath the surface. The superficial extent, however, of earthquakes need not create a difficulty in the present day, when we are aware of the vast distances to which sound and other vibratory motions may be propagated along the substance of solid bodies, and are therefore at liberty to consider the minor effects of an earthquake, to be merely the undulations of the principal shock, propagated laterally through the strata of the Earth.

Gay Lussac observes, that the shock produced by the head of a pin at one of the ends of a long beam is distinctly transmitted to the other extremity, and thence infers the vast distances, to which that communicated by elastic vapours, suddenly generated, and struggling for escape, might be expected to extend.

This consideration, whilst it renders us cautious as to inferring the existence of volcanic action in every spot where earthquakes are experienced, will enable us to reconcile their phenomena with the more moderate depth, which we are induced from other reasons to assign to volcanos themselves.

Upon the whole, then, we are disposed to regard earthquakes as exclusively of volcanic origin, and consequently to appeal to them, as indicating, in the parts where they manifest themselves in their greatest intensity, the operation of subterranean fire, regarding the minor shocks as mere undulations of the strata, occasioned by the primary impulse communicated.

Thermal Waters.

Another class of phenomena, which, like earthquakes, are manifestly connected with volcanos in some instances, but may appear of doubtful origin in others, are hot springs; but we confidently expect, that a brief review of the nature of their contents, of the situations in which they are found, and of other circumstances belonging to them, will lead to the same conclusion, to which we arrived in the former instance.

The solid contents of thermal waters, being obviously derived in most instances from the rocks through which they have percolated, afford little either to confirm or to refute this opinion; but the gases which accompany them are plainly to be traced to the immediate source of the heat, and are given off by the processes to which the latter must be referred.

The Gases given out by them.

Now if it should appear, that the same aeriform fluids are evolved from hot springs, which appear to be emitted by volcanos, a presumption will arise highly favourable to an identity in their respective origins, which will obtain a greater degree of force, in proportion as the gases are generated less commonly by other natural processes.

Thus sulphuretted hydrogen is an ordinary accompaniment both of volcanos and of thermal waters; but the argument drawn from its presence is weak, because the same gas often occurs in springs possessing only the medium temperature, as the effect of processes totally unconnected with volcanic operations.

The same remark applies to the carbonic acid so frequently present in springs, in a proportion exceeding that in which it would be imparted to them by the atmosphere.

Its frequent connection with volcanos is unquestionable, for there are scarcely any, that do not evolve it, either alone, or through the medium of the springs contiguous; but as any cause, which was adequate to impart heat to the water, might equally produce an evolution of carbonic acid from calcareous and other rocks which contained this ingredient, the proof in the above instance is not stronger than it would be without it.

But there is a third description of air evolved from springs, the presence of which seems better calculated to establish their connection with volcanos, since, unlike the first, it is disengaged in a state of purity by no other known process going on in the interior of the Globe, and unlike the latter, cannot be accounted for, in many instances at least, by the mere action of heat on any of the constituents of the surrounding rock formations.

The gas alluded to is nitrogen, which was detected by Sir H. Davy in the white vapour given off by Vesuvius after its eruption in 1819, mixed with only half its usual quantity of oxygen, and by his brother Dr. John Davy in one sample of gas which he collected near the new volcanic Island off Sicily. Its existence, however, in volcanos is more fully substantiated by the ammoniacal salts copiously evolved by many of them; and it is given off from springs, which so manifestly derive their temperature from their contiguity to the latter, that we can scarcely help placing this gas amongst the commonest products of volcanos, during the more languid conditions of their action. Thus it has been observed by a recent chemist, proceeding in large quantities from a spring at Castellamare, in the Bay of Naples; by Professor Daubeny, mixed with a predominant portion of carbonic acid, in the hot springs of Mont Dor and Bourboule in Auvergne, and in those of Chaudesaigues in Cantal; and by M. Longchamp at Vichy: all places, be it observed, so connected with the extinct volcanos of Auvergne, that the heat of the springs must, in these instances at least, be referred to a volcanic source.

Now the gas evolved from the thermal waters of the Alps, however distant they may be from volcanos in action during the present condition of the surface, seems to be generally of the same description; the carbonic acid, which may probably have accompanied it, being in these cases absorbed by the water through which it had to pass.

Thus Professor Daubeny discovered it on the Savoy side of that chain, issuing in large quantities from the spring of St. Gervais; and on the Italian side, from those of Sainte Marguerite at Cormayeur, of St. Didier in the same valley, and of Bonneval in the Tarantaise, half-way between the Bourg St. Maurice and the Col de Bonhomme. In only one of these springs did carbonic acid appear to be present, and in this case it amounted to about 12 per cent. of the whole quantity emitted.

Dr. Ure also mentions his having detected azote issuing in a state of purity from the baths of Loueche in

Swisserland. In this Country, the same gas has long ago been detected in the thermal waters of Bath and Buxton; and more recently it has been found by Professor Daubeny in those of Bakewell and Stoney Middleton in Derbyshire, and that of Taafe's Well in South Wales.

In other portions of the Globe the same gas has been noticed in the thermal waters there met with. Thus Dr. Davy detected it in a state of absolute purity issuing from certain warm springs near Trincomalee in Ceylon, and Boussingault and Rivero in certain ones occurring in the primitive chain of the Cordilleras in Venezuela. (*Annales de Chimie*, vol. xxiii.) It is remarkable, however, that M. Boussingault has since examined certain hot springs in immediate connection with the volcanos of Equinoctial America, and finds them to give out no azote.

The quantity of this gas emitted in a given time is often very remarkable; but the only attempt to obtain a correct estimate of its amount, with which we are acquainted, is that by Professor Daubeny, with respect to the thermal waters of Bath, detailed in a Memoir read before the Royal Society in December, 1833.

It appears, from an average of twenty-four observations made on different days of September and October in that year, that the quantity of gas emitted per minute from the King's bath alone was 267 cubic inches, or about 222 cubic feet in the twenty-four hours. This consisted of about 97 per cent. of nitrogen, and 3 per cent. of oxygen. There was also found a quantity of carbonic acid, varying from 4½ to 13 per cent.

The quantity of gas emitted differed a little from day to day, but the variation did not appear to depend upon the state of the barometer or other atmospheric changes.

Thermal Waters.—Their Situation.

The situation of many hot springs tends also strongly to confirm their relation to earthquakes and other physical convulsions, thus connecting them with the same series of natural phenomena.

Where not placed in the vicinity of active or extinct volcanos, (which is the case with the greater number,) some evidence of violence, some rending or dislocation of the contiguous rocks, may often be perceived. Thus they abound near the base of certain chains of mountains, which, in their highly inclined strata, give evidence of having been heaved upwards, but are comparatively rare in the low country, at a distance from those great centres of elevation, where the nature and position of the rocks indicate no changes, excepting those which may have been brought about, either by the sudden and violent, or the slow and continued, action of water.

If, as in England, thermal waters also occur at a distance from any of the great systems of elevation alluded to, it will generally be found, that the spots themselves exhibit proofs of violent, though more local, convulsions having, at some period or other, taken place in their vicinity.

For instances of this kind, derived from other Countries, we may refer to Professor Daubeny's *Memoir on Thermal Waters*;* on the present occasion, want of space compels us to confine ourselves, to one or two facts drawn from the Geology of England.

Thus the defile, from which issues the tepid spring of St. Vincent's Rocks, near Clifton, is considered by the best observers as the result of some internal derangement of the strata, brought about by disturbing causes of great antiquity; and in like manner, the similar gorge at Matlock, out of which its tepid springs issue, is associated with a great dislocation of the strata, attributable to their having been tilted upwards at an high angle to the West.*

The same fault has been traced by Mr. Farey as far as Buxton, and from thence to the villages of North Bradwell and Stoney Middleton, in all which places have been noticed springs, possessing a temperature more or less elevated above the medium point of that climate.

We must not, indeed, expect to meet with the same direct evidence, in the case of every hot spring that comes under our examination. At Bath, we know of no dislocations in the strata posterior to the age of the coal and mountain limestone, and it would, perhaps, be rash to connect these with the cause of the thermal waters there existing. Nevertheless, when we consider, in how very large a proportion of cases some indication of an igneous character may be traced, the absence of proof in the few remaining ones may, perhaps, be fairly referred to the imperfection of our knowledge.

The volcanic nature of thermal waters is likewise confirmed, by the relation which seems to subsist in general between the elevation of their temperature, and the date, which we should be induced from other considerations to assign, to the latest manifestations of volcanic agency in the country.

Thus, those which make the *nearest approach* to the boiling point of water, are uniformly found amongst volcanos now in action; next in the order of temperature are those associated with volcanos, which, though now extinct, appear to have existed at a period, Geologically speaking, recent, that is, at a time when the great features of the country were nearly as at present; whilst the springs, which gush out at the foot, or in the midst, of uplifted chains of mountains, at a distance from those rocks which are generally regarded as volcanic, never possess a temperature so elevated, as the two preceding classes of thermal waters sometimes attain to.

Now, if these latter were really produced by other causes than volcanos, it does not seem intelligible, why they should, in all cases, observe that lower degree of heat, which indicates, either a cause of less intensity, or one whose effects have been moderated by a longer intervening space of time.

Lastly, the other solutions of the heat of springs appear on examination totally inadequate to account for their phenomena. In the case of the Bath waters, indeed, the warmth has been attributed to the decomposition of pyrites, in which the lias clay, from whence it issues, abounds; but to this it may be objected, that the same stratum, though equally charged throughout with this mineral, nowhere else throws out springs possessing more than the medium temperature; and yet, the sulphuretted hydrogen, which the latter so frequently contain, shows a decomposition of pyrites to be going on in several other places. Besides, it is remarkable, that thermal waters, far from being impregnated with those saline ingredients, which would naturally enter into their constitution, if they were caused by the heat generated in consequence of such chemical processes taking place in the interior of the Earth, are, on the contrary, in the great majority of instances, remarkably free from foreign matter. Thus the Bath waters contain not a particle of the sulphuretted hydrogen, or sulphate of iron, which would have arisen from the decomposition of pyrites; and the mineral contents of those connected with primitive chains, such as the Alps or Pyrenees, although obviously referable to the action of water, assisted by heat and pressure, upon felspathic rocks, are far from suggesting any distinct chemical operation, by which this heat could have been elicited.

---

* *Edinburgh New Philosophical Journal*, Oct. 1831.

* A striking instance of the same kind, taken from the Pyrenees, is exhibited in pl. v. fig. 8. at a place called St. Paul de Fenouilhades, Dep. des Pyrénées Orientales. We there see a thermal spring gush out from a narrow gorge in an elsewhere continuous line of hills, the strata of which lose their horizontality and sink abruptly on both sides towards the fissure.

Upon the whole, without pretending, that the evidence in the case of thermal waters is so conclusive as in that of earthquakes, or denying, that there may be instances, in which springs have acquired an extraordinary temperature from local causes of a different kind, we hold, that their existence affords a strong indication of subterranean processes similar to those, which, on a more extended scale, gave rise to earthquakes, especially wherever we observe such a continuous and connected range of them to occur, as that which we find encircling the base of particular chains of primitive mountains, or associated with certain leading systems of elevation.

Evolution of Carbonic Acid.

There is yet another natural phenomenon closely connected with the subject of thermal waters, which remains to be considered—we mean the evolution of carbonic acid from the interior of the Earth, either alone, or accompanying certain springs.

The relation of this to volcanic processes may be established by a similar line of argument to that we have pursued in the former instance, namely, by pointing out its frequent occurrence, in conjunction with thermal waters, and in situations which have undergone certain physical convulsions.

Thus the same country, which throws out warm springs at a low level, and at a point more contiguous to the supposed focus of the volcanic action, affords cold carbonated ones at a higher level, or at a point more remote. The hot springs of Ems and Wiesbaden, for instance, are found near the base of the Taunus mountains, whilst the cold effervescing ones of Schwalbach and Fachingen occur higher up in the same chain; thus, too, the same district which gives rise to the thermal waters of Aix la Chapelle, furnishes the chalybeates of Spa near the summit of the hills above. The connection of carbonated springs with faults may be observed in Derbyshire and Yorkshire, but it has been more satisfactorily traced in Germany, where they have been found to issue from what have been termed circular valleys of elevation; that is to say, valleys which are, or appear at one time to have been, enclosed by escarpments, the strata dipping away in all directions from the centre towards the circumference. Several valleys in Westphalia exhibit this remarkable structure, and none more strikingly than that, in which the cold chalybeate of Pyrmont is situated. In this instance the rocks are composed of the variegated sandstone, the muschelkalk limestone, and the keuper, which are seen overlapping in the hills bounding the valley, but dipping in opposite directions on opposite sides of it, so as to present every where escarpments fronting each other. (See pl. v. fig. 7.) From the bottom of the valley carbonic acid is constantly issuing in large quantities, impregnating the springs of water, and accumulating in dry pits and caverns. The valley of Dryburg, and other spots in the same country, noted for the occurrence of cold carbonated springs, exhibit a similar conformation in their strata.

Rullman, in his description of Wiesbaden, remarks, that in the neighbourhood of the carbonated springs which so abound in the Duchy of Nassau, the rocks are subject to remarkable changes in their dips, to saddle-shaped stratification, and to fractures. The character of the rock is also frequently more friable near the mineral springs.

Professor Buckland, in his *Memoir on Valleys of Elevation*, published in the *Transactions of the Geological Society*, had previously pointed out the occurrence of such valleys in England; and it may be worth remarking, though as an isolated fact, perhaps, not of much weight, that the most important of our chalybeates, that of Tunbridge, is found in this kind of situation.

Now the relative position of the strata in these valleys just as obviously suggests the idea of their having been affected by some convulsion of Nature, as the highly inclined rocks of Alpine Countries; and it is impossible to conceive, either that they could have been deposited in the first instance at so high an angle, and with such a variety of dips, or that there should have been such a coincidence between the elevation of their escarpments on the opposite sides of the valley, if the beds had not once been in continuity.

It may be inquired, whether even those accumulations of carbonic acid, which take place so frequently in neglected mines and wells, and which have imposed the necessary precaution of letting down a light before we venture to descend into them, may not be owing to a slow evolution of this gas from fissures beneath, in which case a volcanic action may be assigned, as, at least, its most probable cause; the law of the rapid diffusion of all gases through the atmosphere precludes the possibility of attributing it to a mere separation of carbonic acid, in consequence of its greater specific gravity, from the other constituents of the atmosphere; and the same cause would quickly dissipate it, even if it were given out by the decomposition of organic matters.

Nevertheless, before we allow ourselves to adopt this opinion, it will be necessary to ascertain, first, whether in these cases any local causes for the production of carbonic acid exist; and, secondly, whether its further generation might, in these cases, be prevented by covering the bottom and sides of the pit with some coating impermeable to air.

Mud Volcanos or Salses.

With regard to those emanations of gas and vapour, which occur in certain Countries, accompanied with eruptions of mud and petroleum, we must withhold our assent to the vulgar opinion, which attributes them to volcanic action, as the name of mud volcanos, by which they are usually designated, seems to imply.

That they are often connected with them, we are not, indeed, disposed to deny, but they appear to be so only in the relation of an effect, produced by the presence of inflammable materials, brought together by the operations of some pre-existing volcano.

That the process itself is distinct from that which takes place in the latter, is evident, from considering that in every case in which it has been examined, the seat of the action is found to be quite superficial, and to reside in a stratum of very recent origin, known to be strongly impregnated with sulphur and petroleum. Such is the case at Macaluba near Girgenti, in Sicily, where the mud volcanos, as they are called, lie quite detached from the true volcanic phenomena of Etna or of the Val di Noto, and seem manifestly dependent on the combustion of the sulphur, which exists in the rock in such quantities as to supply all Europe with that material.

The same is likewise the case with the "Salses," or mud volcanos of Modena, which lie at a distance from every genuine burning mountain; and, according to Humboldt, with those of New Andalusia and the Island of Trinidad. The phenomena exhibited by those in Sicily, and amongst the Subapennine Hills, are in general of a very insignificant kind, consisting of a mere evolution of water mixed with mud and bitumen in consequence of the disengagement of gas, apparently consisting of carbonic acid and carburetted hydrogen, from little circular orifices on the summit of the hill. Ordinarily, nothing but a bubbling up of gas from the interior of these craters is to be observed; but it is said, that there are times, at which the process has been known to go on with considerable energy, for the mud has been thrown up in Sicily to the height of 200 feet, accompanied with a strong odour of sulphur.

In the little Island of Taman, which connects the chain of mountains traversing the Peninsula of Crimea with the Asiatic Continent, the process in question seems to be proceeding on a more extensive scale. Pallas represents occasional eruptions as taking place from certain crevices in the rocks of this Island, which began with a thick smoke, followed by a column of flame fifty feet in height, which continued in one instance for eight hours and a half incessantly, during which time streams of mud flowed in all directions, but no lava or altered masses of stone were ejected. The accounts given by Mr. Heber, in his Manuscript Journal attached to Dr. Clarke's *Travels*, fully confirm this view, and render it highly probable, that the phenomenon is altogether analogous to that of Macaluba in Sicily, and of the Salses near Modena.

Assuming, therefore, these latter as the best types we possess of mud volcanos, and reasoning from them to the rest, it will probably appear, that all the phenomena they exhibit will admit of explanation from the mutual action of certain substances, originally accumulated in submarine solfataras by antecedent volcanic processes, the result of which would be the extrication of carbonic acid, and of an inflammable gas arising from the slow distillation of bituminous matters, together with the rise of water, through the channels originally established by the gases discharging themselves upwards. That volcanic action is not necessarily the cause, is shown by finding a similar phenomenon described as occurring in the Western States of Ohio, where it seems quite unconnected with any such cause.

In this spot the salt springs, which so abound, are found to be constantly giving rise to an evolution of carburetted hydrogen gas, accompanied with much petroleum. The jets of gas are sometimes so forcible, as to throw the water entirely out of the spring.

There seems, therefore, no necessary connection between such phenomena and our present subject, and their more frequent occurrence in rocks which lie in the neighbourhood of volcanos may be readily accounted for, by the tendency of the latter to bring together materials proper for carrying on such operations.

Emanations of Inflammable Gas.

Still less are we disposed to attribute to a volcanic cause the emanations of inflammable gas, which are occasionally seen issuing from the crevices of rocks, in a continued, and, according to our limited notions of time, an unfailing current.

The evolution of carburetted hydrogen from the cracks and crevices of coal mines, enables us to conceive, by what natural processes such a phenomenon may be accounted for, and the recent discoveries, with respect to the liquefaction of the gases, render the regular and lasting discharge of such a stream of elastic matter more intelligible. Now the phenomenon in question, when divested of the marvellous, reduces itself simply to this, for it is a mistake to imagine, that the flame is self-kindled, at least in the instances that have been well examined, although, when the gas is once set on fire, the supply is sufficiently regular to keep up a continued combustion.

The most noted instances of this phenomenon are at the Pietra Mala, on the summit of the Apennines, between Bologna and Florence; at a place called St. Barthelemi, near Grenoble;* and in the Chimariot mountains in Albania, where it is probable that it has continued for the last 2000 years, for many ancient writers speak of a Nympheum on the coast of modern Albania, near Apollonia, celebrated for the flames that rose continually from it, and Dodwell's authority establishes the existence of the same at the present day in that country.

It is probable, that the phenomena which occur at Baku on the Western side of the Caspian, where the soil is strongly impregnated with petroleum, are connected with these last-mentioned causes, rather than with those of genuine volcanos.

There is indeed a report given of an eruption, which took place in that Province in the year 1827, but from the description it would seem to amount to nothing more, than a combustion of bituminous matters on a larger scale than usual. It is said, that a vast column of fire rose to an extraordinary height, maintaining itself at the same for three hours, after which it gradually diminished to twenty inches; the fire extended itself over a tract of ground 1300 by 1900 feet in diameter. At the time of the first eruption red-hot stones and volumes of water were ejected. No appearance of a crater was to be perceived, but the spot, whence the column of flame rose, was elevated about two feet above the general level of the plain. The surrounding tract resembles a ploughed field, and is covered with a variety of anomalous products of heat. There are, however, no ejections of water, nor any of those sulphureous exhalations, which are commonly met with in such cases, as at Macaluba, and in the other so called mud volcanos.

SECTION 3.

Theories of Volcanic Operations considered.

The phenomena, therefore, to which we feel warranted in appealing, as indications of igneous action going on in the interior of the Globe, are those of volcanos, earthquakes, thermal waters, and emissions of carbonic acid gas; and in order to estimate the amount of the changes that may have been brought about on the crust of the Earth by their united operation, it will be necessary to inquire with respect to the probable cause of these internal commotions, as a clew not only to guide us concerning their present action, but likewise as to the probability of their more or less extended influence in periods that have gone by.

---

* The writer of this Article visited this spot in 1830, and found that the flame rekindled when merely blown out, but that it could be extinguished by throwing water over it several successive times. The gas was collected and burnt, and water and carbonic acid were the results.

The theories which have been propounded, with the view of accounting for the existence of volcanic action, may be divided into two classes; those which assume some chemical process, of which the heat is merely an effect, and those which, assuming the existence of the heat, deduce the other phenomena from its presence.

In the former, in short, the heat is *one* of the effects; in the second, it is the cause of *all* the phenomena observed.

The theories, however, which belong to the former of these classes, though agreeing in this one particular, that of imagining combustion of some kind to have caused the heat, differ widely as to the material which excited it; coal, petroleum, and sulphur, having all at times been assumed as the main agent concerned in the process.

But these substances have been shown, not only to be in themselves totally inadequate to explain the phenomena, but to be productive, when set on fire, of a train of effects altogether different from those of genuine volcanos; witness those arising from the accidental burning of coal mines in many parts of Great Britain, of masses of petroleum, as at Baku, or of sulphur and bituminous matters, as at Macaluba.

Accordingly it is now generally admitted, that no processes going on near the surface are calculated to produce the phenomena of volcanos; and that if the latter arise from combustion, the materials which occasion it must, in part at least, be of a different description from the combustibles which exist in a natural state within the sphere of our observation, since in order to consume oxygen without substituting for it a corresponding amount of some gaseous oxide, the products must be of a fixed nature, which is not the case in our artificial fires.

Recent discoveries have, however, convinced us, that the whole of the crust of the Earth contains principles, which in their uncombined state are in a high degree inflammable, and which, for this very reason, never occur to us, except in union with oxygen. Such are the alkalies and earths, which Sir H. Davy has shown each to contain a metallic basis, a body capable of abstracting oxygen, both from common air and from water, and giving rise at the time to a sufficient extrication of light and heat, to constitute a case of genuine combustion. There must have been a time, therefore, when these substances existed uncombined with oxygen even on the surface, and there is no reason to deny, that the process of oxygenation may still be incomplete at those vast depths, when air and water are admitted but slowly, or at distant intervals.

There seems therefore no *à priori* absurdity in imagining, that volcanic action may consist in a process of oxygenation, caused, in part at least, by the presence of these substances, and all that seems necessary, is to ascertain, how far the known phenomena accord with such an hypothesis.

The other class of theories, which assumes the high temperature, and then deduces from it the phenomena, seems at first sight to have an advantage over the preceding one, inasmuch as the existence of an internal heat may be said to be in a manner ascertained, whilst that of the alkaline and earthy metalloids, uncombined with oxygen, is at most only probable; and accordingly many have been induced to prefer this mode of accounting for the phenomena, as less hypothetical and requiring fewer postulates.

They forget, however, that the existence of an internal heat is assumed alike on either supposition, and that the true point of dispute is, whether it can best be explained by the presence of a melted or ignited mass in the interior of the Globe, or by a process of oxygenation going on in its constituents.

Now the only distinct argument in favour of the internal fluidity of the Globe, is deduced from its figure, which has been proved to be that of an oblate spheroid; a form, it is contended, which could not have been imparted to it, had it not been originally in a liquid state, and from thence the advocates of the above hypothesis conceive themselves at liberty to infer that it is so at present.

Neither of these propositions, however, can be regarded as demonstrated. Sir J. F. Herschel has shown, in his *Treatise on Astronomy*, that the oblate figure of the Globe may only have arisen from its long continued rotation, this being the point to which, under this condition, it must tend, and which it would ultimately attain, even as its surface is at present constituted.

Neither, if we grant the Earth to have been originally fluid, is there any direct proof, that it must have continued so till the present time; for the increased temperature observed at the slight depths to which man has penetrated below the surface, only proves, that the temperature of the crust is higher than that of its superficies, not that it is considerable enough to retain the substances of which the interior is made up in a state of fusion.

The proper mode, however, of considering the question seems to be, not to lose ourselves in conjectures, as to what may by possibility be the condition of the Globe at inaccessible depths, but to pass in review the actual phenomena of volcanos, and see, whether we can best deduce them, from the mere effects of the protrusion of a melted mass of matter, or from a process of combustion, originating in materials which may still exist in an unoxidized state below.

In order, however, to determine this, it will be necessary to consider at some length, first, the geographical situation of volcanos; secondly, the character of the substances evolved by them in a gaseous state, and of the products resulting; and thirdly, that of the lavas and other matters ejected in a solid or liquid condition: from whence we shall be led to examine, the depth at which volcanic action is seated, and lastly, the mode in which the mountains, are built up of materials before considered.

Geographical Distribution of Volcanos.

Volcanos are said by Von Buch, either to occur scattered at certain distances along particular *lines* of country, or else to be united in clusters around some common centre.

The former he calls linear, the latter central volcanos; and whilst he regards the linear, as being in general produced in the direction of the fissures caused by the igneous operations of a former period, over which the primary ranges of mountains have been upheaved, he considers the central, as taking place in all kinds of positions over the Earth's surface, however much detached they may be from any of those leading systems of elevation, wherever the force which has been set in motion by volcanic agency is able to overcome the resistance opposed by the superincumbent rocks. In the former case the direction taken by the volcanic forces is determined by the previous configuration of the country; in the latter it takes place without reference to the nature of the pre-existing rocks.

It may, perhaps, be doubted, whether even the central volcanos enumerated by Von Buch, may not in some instances at least admit of being referred to some common system; but there can be no question, that the law which he has laid down with regard to the tendency of volcanos to burst forth in certain lines of country rather than in others, holds good very generally, and that many such groups may be enumerated; such as, that already pointed out as extending across the Greek Islands; (see pl. vi. fig. 5;) that stretching across Mexico, (pl. vi. fig. 3;) and still more remarkably the one, which, beginning at Burren Island, in the Bay of Bengal, may be traced along the Islands of Sumatra and Java, thence to the Philippines, and perhaps even to the Kurule Islands and to Kamtschatka. (See pl. vi. fig. 4.) The linear direction, therefore, of certain volcanic formations cannot be doubted; and the only question is, whether it prevails universally, or characterises, as Von Buch conceives, one particular class only of burning mountains.

Proximity to the Sea.

Another remarkable feature in the distribution of volcanos is their proximity to the sea; in proof of which it may be sufficient to remark, that out of a catalogue of no less than 163 active vents enumerated by M. Arago as occurring in various parts of the known World, all, excepting two or three in different parts of America, and about the same number, of which we possess very imperfect information, in Central Asia, are within a short distance at least of the Ocean.

It is even found, that the very excepted cases, when examined, tend to confirm the rule; being so situated, that their connection, either with the Ocean, or with inland seas that may supply its place, becomes a matter of fair inference. In proof of this we need only refer to the descriptions we have already given of Jorullo; from which it appears, that distant as this mountain may be both from the Atlantic and Pacific Oceans, it is nevertheless connected with one or both through the medium of a chain of volcanic eminences; (see pl. vi. fig. 3;) and even the volcanos of Tartary, whose existence in an active condition is more problematical, may be connected with some of those extensive salt lakes, which seem to abound in the depressed portion of Central Asia.

Thus even those few cases, which may be brought forward as exceptions to the general rule, appear, when examined, to enter into it, so far as relates to the probable connection they denote with deep seas or lakes; whilst the occurrence of by far the majority of active volcanos in Islands and maritime tracts, and their entire absence from many extensive Continents, may convince us, that the processes are at least greatly promoted by such a position, and in their intensity bear a certain relation to the more or less ready access to them of water.

And, although extinct volcanos seem by no means confined to the neighbourhood of the present seas, being scattered often over the most inland portions of our existing Continents; yet it will appear, that at the time at which they were in an active state, the greater part were in the neighbourhood of those extensive salt or fresh-water lakes, which existed at that period over much of what is now dry land. Instead, therefore, of these being brought forward as exceptions to the generality of the rule, the cessation of such action, now that the water has left their neighbourhood, seems to furnish a confirmation of its truth.

Aeriform fluids evolved.

We have next to consider the ordinary products of volcanic operations, and shall begin by noticing the aeriform fluids evolved, regarding them as in a manner the prime movers of the effects we witness, the agents, by whose mighty power are propelled from the bowels of the Earth those solid matters, afterwards to be described, which, settling round the brim of the orifice from which they found an issue, grow at length into the form and dimensions of an ordinary crater of eruption.

During the active condition of a volcano, the aeriform fluid most copiously emitted probably is steam, which manifests itself in those white vapours which usually proceed from the crater during an eruption, and may assist in producing by its condensation the heavy rains which frequently succeed it, though we are more disposed to attribute these to the disturbance in the electricity of the atmosphere, which is evinced by the vivid lightning commonly observed during a volcanic eruption.[*]

Steam is also emitted, sometimes for ages together, from fissures called "stufas," on the flanks of many extinct as well as active volcanos; thus supplying us with a confirmation of the dependence of volcanic phenomena upon the presence of water.

The permanently elastic fluids commonly given out are, muriatic acid, sulphuretted hydrogen, sulphurous acid, carbonic acid, and nitrogen.

Of these the first, muriatic acid, seems to be generated during almost all the phases of volcanic action; for although some have attempted to establish a class of volcanos to which the production of muriatic acid was peculiar, yet it would seem that there were none from which this gas is not in greater or less quantity disengaged.

Thus it has not only been detected by Sir H. Davy, issuing from the flanks of Vesuvius soon after the eruption of 1815, but likewise from the same mountain whilst in a more quiescent condition in 1824.

It was also found by Professor Daubeny, in the vapours given off round the crater of the Island of Volcano, round that of Etna whilst dormant, and in that of the Solfatara of Puzzuoli; it has been discovered also in the volcanos of Iceland; in those of Java, at Mount Idienne; and of South America, at Puracè, accompanied in both these latter cases with a predominant proportion of sulphuric acid; nay, it has even been found in an uncombined state pervading the trachytic rock of the Puy di Sarcouy in Auvergne. Of the gaseous compounds of sulphur, one, the sulphurous acid, appears to be predominant chiefly in volcanos possessing a certain degree of activity, whilst the other, sulphuretted hydrogen, seems to be emitted for the most part when they are in a dormant condition.

---

[*] Sir H. Davy, in his Memoir on Vesuvius, remarks that it was easy, even at a great distance, to distinguish between the steam disengaged by one of the craters, and the earthy matter thrown up by the other. The steam appeared white in the day, and formed perfectly white clouds, which reflected the morning and evening light of the purest tints of red and orange. The earthy matter always appeared as a black smoke, forming dark clouds, and in the night it was highly luminous at the moment of the explosion.

Thus sulphurous acid is given off in large quantities from the craters of Etna and Vesuvius, and even from that of Volcano in the Lipari group, whilst sulphuretted hydrogen is observed at the Solfatara of Puzzuoli, on the skirts of Etna near Jaci Reale, and in many hot springs connected with dormant volcanic action both in these regions and elsewhere.

Not that we are obliged to suppose sulphurous acid to be entirely absent in the latter cases, or sulphuretted hydrogen in the former; for as these two gases, when they meet, decompose each other, forming water and depositing sulphur, it is reasonable to expect, that only that portion of either which exceeds the quantity necessary for their mutual decomposition will escape from the orifice, so that the gas that actually appears, only indicates the predominance of the one, and not the entire absence of the other.

Carbonic acid appears to be chiefly found in volcanos that have become extinct, and when it occurs in those considered active, it is at a time when they are not in a state of eruption. It is also found to occur more commonly at the foot and in the neighbourhood of volcanic mountains, than in their craters, or at the points of their most vehement action; so that it may be viewed, rather as one of the consequences of a long continued operation of the heat produced upon the contiguous rocks by volcanic processes, than as the direct effect of the processes by which that heat is occasioned.

The last of these gases, nitrogen, has been already sufficiently alluded to: from the observations hitherto made, it would seem to be for the most part the concomitant of languid volcanic action; but it is probable, that, when the gases evolved from active volcanos have been scrupulously examined in a greater number of cases, it will be noticed much more commonly as occurring amongst them; since Sir H. Davy detected it, in Vesuvius, and his brother Dr. John Davy, in the gas given off by the new volcanic Island near Sicily, in both cases accompanied with less than the usual proportion of oxygen.

Substances not gaseous ejected.

Other substances are often disengaged from volcanos as vapours, but condense round its exterior either in a liquid or a solid condition.

Such is the petroleum found by Breislac, at the foot of Vesuvius, the Val di Noto in Sicily, the extinct volcanos of ancient Latium and Auvergne, the site of the ancient eruption recorded in the Book of *Genesis* on the spot now occupied by the Dead Sea, and many other localities. Such also is the sulphuric acid, which has been only hitherto met with in extinct volcanos; as for instance in a stream issuing from that of Purace between Bogota and Quito, from one derived from Mont Idienne in Java, and probably in the rocks connected with the languid operations about Radicofani in Tuscany. It is obviously derived from the sulphurous acid, which, passing through the water of some volcanic lake, and absorbed by it, has derived an additional dose of oxygen from the atmospheric air present.

The solid substances sublimed by volcanos are, 1. the boracic acid, found in the crater of Volcano, and the Lagunes of Tuscany, which, though it remains fixed in our furnaces, appears to be evolved in vapour by the heat of these volcanos. 2. Muriate of ammonia, very abundantly evolved during certain eruptions, as by that of Etna in 1780, but apparently absent from others. 3. Specular iron ore, probably disengaged in combination with chlorine, which latter principle may be separated, on its coming into contact with the atmosphere, by means of the heat, water, and oxygen of the air. 4. Muriate of soda, the most abundant of them all, as well as the most universal, being exhaled more or less by almost all volcanos, and present even in their lavas, according to Monticelli, who obtained more than nine per cent. of it, by simple washing, from that which issued from Vesuvius in 1822.

We do not include among the sublimations, the deposits of sulphur, or the sulphurets of iron, copper, arsenic, and selenium; still less the various sulphuric salts found efflorescing in the spiracles of all volcanos.

The sulphur, which seems to be of almost universal occurrence wherever volcanic operations are going on, is evidently derived, in the majority of instances, from the mutual decomposition of the sulphurous and sulphuretted hydrogen gases; for we know of no well authenticated case of its sublimation in an uncombined state from any volcano, and analogy would lead us to extend the same inference, to the compounds of sulphur with arsenic and selenium, that occasionally accompany it.

The sulphates of lime, alumina, iron, magnesia, and soda, which so frequently incrust the surfaces of recently ejected masses, or the fissures of volcanos in present action, are evidently produced, by the affinity exerted by the sulphuric acid, which has proceeded from the sulphurous acid disengaged, for those alkaline and earthy bases with which it may have come into contact.

The substances hitherto considered, in whatever condition they may present themselves to the eye of the observer, have evidently been either disengaged from the volcano in a gaseous form, or at least have resulted from the same; but we have next to consider those, which have been thrown out in a solid or a liquid state from the crater, but without becoming, like the former, volatilized by the action of the heat.

Solid Substances ejected.

They may be divided, into such as have undergone a complete change from the process, amongst which we comprehend lavas, and loose ejected masses of similar composition; and such as are thrown out, either unaltered, or at least retaining enough of their original characters, to be identified with some one or other of the existing rocks.

Lavas.

Their Chemical Characters.

Beginning with the former class of substances, I shall first state the chemical, and afterwards the mineralogical characters of lavas.

Lava, when observed as near as possible to the point whence it issues, is, for the most part, a semifluid mass of the consistence of honey, but sometimes one so liquid as to penetrate the fibres of wood. It soon cools externally, and therefore exhibits a rough unequal surface; but, as it is a bad conductor of heat, the internal mass remains liquid, long after the portion exposed to the air has become solidified. The temperature at which it continues fluid is considerable enough to melt glass and silver, and has been found to liquefy in four minutes a mass of lead of such a size, as, when placed on red-hot iron, to require double that time to enter into fusion.

Stones of a spongy nature, pumices probably, were melted when thrown into the lava of Vesuvius; that of Etna is said to have effected the same; and a current, which proceeded from an Iceland volcano, is stated to have melted down every kind of hard stone that came in its way.

On the other hand, masses of limestone have been taken out from the midst of lava with no signs of fusion upon them, and even with their carbonic acid undiminished; and the houses of Torre del Greco, and of other villages, which have been enveloped in liquid lava, remained unmelted by it. When bell-metal was submitted to the action of the Vesuvian lava of 1794, the zinc was separated, but the copper continued unaffected.

Sir James Hall, in his Memoir on Whinstone and Basalt, has presented us with a Table of the relative fusibilities of seven specimens of whin or basalt from the neighbourhood of Edinburgh, and of an equal number of lava from various European localities; from which it appears, that when converted into the state of glass, they become softened at a temperature from 15° to 24° of Wedgwood, or 3027° to 4197° of Fahrenheit. Whilst in a crystalline state, the same ingredients continued solid at this temperature, but became soft at one varying, from 28° to 55° of Wedgwood, or from 4717° to 8227°, a heat inferior to that of a common glass-house.

With this statement regarding the melting point of these ignigenous products, the chemical composition, which appears to belong to them, is in complete accordance.

According to Dr. Kennedy, two specimens of the lava of Mount Etna contained each 4 per cent. of soda, and nearly 15 of oxide of iron, to 51 of silex, 19 of alumina, and about 10 of lime. Other lavas, doubtless, are differently constituted, and some appear to be completely destitute of alkali; yet even in these latter cases the presence of some alkaline earth, capable of acting as a flux to the silex and alumina, seems universally to supply its place; and accordingly, there are few varieties, that do not readily fuse at the heat of an ordinary blast furnace, and some, indeed, at a much lower temperature.[*] Nevertheless, there are circumstances, which have induced certain Naturalists to adopt quite a different view of the nature of lavas, and to imagine them to owe their fluidity, not to the intensity of the heat, but chiefly to the presence of some solvent or flux.

This opinion was originally broached by Dolomieu, who founded it upon the assumption, now admitted to be erroneous, that the crystals of augite and hornblende which lava contains, existed antecedently to the fusion of the mass, and were not produced in consequence of it. Hence he necessarily concluded, that the lava could only have been subjected to a degree of heat, inferior to that at which such crystals would become fused.

Finding, therefore, sulphur to be exhaled from certain lavas, he imagined this to act as a flux to the other substances, and accounted for the more difficult fusibility of the mass when once cooled, from the escape of the sulphur originally present. The existence of sulphur in lavas has been asserted by some, and denied by others, but whether it be present or not, there seems no necessity for attributing to it the fusion of the mass, when, as we have seen, its composition alone sufficiently accounts for this circumstance.

It must in any case be disengaged very soon after the melted matter has been ejected, for no sulphurous vapours are perceived to issue from a lava current of old standing, even though it may continue internally fluid; and it is well known, that sulphur forms no part whatever of the composition of lavas, and can, therefore, only be mechanically mixed with them.

A recent Geologist has lately brought forwards a modification of Dolomieu's theory, by supposing water to act the part which the latter attributed to sulphur; and although we are compelled to reject his theoretical views on this subject, as utterly inconsistent with known chemical principles, yet they suggest some interesting inquiries, with respect to the state in which those volatile matters existed in lava, which are said to be copiously disengaged from it in the state of vapour. Have they been confined by the pressure of the superincumbent mass, until its gradual cooling caused fissures by which they were enabled to make their escape, or is it possible, that the influence of pressure may be assisted by some kind of chemical union between them and the other constituents? All writers admit, that various salts are emitted from the surface of recent lava, which are never found amongst its constituents; and if these are sublimed, as appears to be the case, by the heat, the same may also happen with regard to the other more volatile matters, whose extrication from lava is vouched for on respectable authority.

Their Mineralogical Characters.

The mineralogical characters of lavas have been already given at the commencement of this Article, where they are stated to belong in general to the rock called by Mr. Scrope greystone, and by M. Brongniart tephrine, consisting essentially of felspar, with many accidental ingredients superadded, such as olivine, mica, augite, hornblende, titaniferous iron, and the like.

Loose Fragments ejected.

The loose fragments ejected from the crater differ but little in mineral composition from the continuous streams of lava, but they are generally of a more cellular and porous aspect, not uncommonly fibrous, and consequently more brittle and incoherent. They also frequently present that vitreous appearance which is the effect of sudden cooling, and vary in size from masses many tons in weight to a fine and impalpable powder.

There seems, therefore, good reason for suspecting, that all those volcanic products which we have just been considering, in whatever form they may have issued from the volcano, are allied to the rock denominated trachyte; and, that they are either derived from it, or, at least, formed out of the same materials as those of which the latter is composed, appears from our finding, that, in many places where the structure of a volcanic mountain has chanced to be exposed, the lowest in the series of formations that present themselves to the eye is of a trachytic nature, and that the strata superincumbent often seem to show a resemblance to that rock, more or less close in proportion to their contiguity to it.

Trachyte, whence derived.

Trachyte, also, is a rock of such universal occurrence in volcanic Countries, and so abundant in those in which the action is of the most remote date, and has taken place on the most extensive scale, that it seems to be natural to derive the lavas subsequently ejected from it, regarding them merely as so many modifications of this original material, more or less changed by the larger continuance of the heat, or the admixture of other matters.

---

[*] According to Saussure, *Journal de Physique*, an. 2, felspar melts at 70° of Wedgwood, basalt at 76°, and hornblende at about 100°.

But, considering the peculiar characters and composition of trachyte, as well as the circumstance of its being limited to Countries that appear to have undergone the action of volcanic fires, we can hardly regard it as a substance which makes a part of the original constitution of the Globe, and shall be disposed to set it down, as itself a product, although a primary one, of the fusion of other kinds of rock. Of what nature this latter may consist, will, perhaps, be determined, if we examine, first, with what particular descriptions of rock trachytes are most connected in point of situation; and secondly, to what they present the nearest resemblance in mineralogical and chemical composition.

The former inquiry will lead us to consider, in the first instance, the nature of those ejected masses which appear to belong to the contiguous rock formations, and not to be products of the igneous operations to which their ejection has been owing.

Among these, we read of no substance bearing the slightest resemblance to the constituents of secondary or tertiary strata, but of many which may, with the greatest probability, be referred to rocks of a granitic character.

Thus at the Puy Chopine in Auvergne, granite is found intermingled with the trachyte and greenstone, thrown together in confusion, as if the whole had been elevated at one time, before the rock had been entirely changed by the process.

In the lavas of the Vivarais, in those of the Rhine, and in other localities, imbedded masses have been met with, having much the appearance of an altered gneiss or granite. Humboldt mentions his having found, in the midst of the new volcano of Jorullo in Mexico,* white angular fragments of syenite, composed of a small portion of hornblende, with much lamellar felspar; Gemellaro discovered a mass of granite containing tinstone amongst the ejected masses of Mount Etna; and the same rock has been discovered amongst the trachyte of the Ponza Islands by Mr. Scrope, and in the lava of Vesuvius by Dr. Thomson of Naples.

Mica slate has, in one instance, been found ejected by Vesuvius, and various granular limestones of a dolomitic character are found amongst the masses ejected from the old crater of Vesuvius, which lie accumulated in the Fossa Grande, and other hollow ways on the slope of the volcano. It must be remarked, however, that these latter are never imbedded either in the lavas or in the volcanic masses ejected, so that they do not stand in the same relation to them, as the granitic masses do which have been before enumerated.

With regard to the formations, in which trachytic rocks, or, to speak more generally, volcanos, usually appear, great discrepancy seems at first sight to exist.

Thus, to begin with the Rhine, the formation on which the trachyte of the Siebengeberge rests, and among which the volcanos of the Eyfel have arisen, is a clay slate belonging to the transition series; in Auvergne, the rocks of Mont Dor and of Clermont rest immediately upon granite, or are separated from it only by a tertiary deposit, whilst those of Cantal are incumbent on mica slate. In Hungary the rock underneath is a porphyry, associated with syenite, clay slate, &c. and referred by Beudant to the transition series; in Transylvania, according to Boué, the trachytes lie near the mica slate and gneiss, with which are masses of syenite and marble; whilst in Styria, the rock most immediately surrounding the little trachytic formation of the Gleichenburg, is gneiss.

In Italy the case is somewhat different; yet, though the trachyte of the Euganean hills rises from beneath chalk, we have reason to believe that primitive and transition rocks lie at no great depth beneath, as they are found near Schio, and support the alternations of volcanic and neptunian deposits in the Braganza.

Humboldt has shown, that the rock which supports the volcanos of the New World is generally a transition porphyry, and sometimes granite or syenite; and Von Buch reports, that the last-named rocks appeared as the lowest of those uplifted strata, which surrounded the crater of the Island of Palma and other of the Canaries. Now, although the preceding enumeration indicates such a variety with regard to the position of volcanic formations as may seem at first sight to baffle all general conclusions; yet when we consider, that, in the majority of instances, the rocks have been referred either to the primitive or the transition series, and that in the remaining ones, the latter were at a depth far less considerable, than that at which we shall afterwards find reason to conclude, that the volcanic force itself resides; it may not be unfair to presume, that volcanos have universally broken out amongst the older formations, or those most near to the nucleus, whatever that may be, of the Globe.

It is obvious, indeed, that in those cases in which volcanos have appeared in the midst of primitive rocks, we cannot presume the seat of action to reside amongst those of a later date, but that the converse does not hold good; so that if we only admit, that any certain position is to be assigned to these products, a single case of their occurrence in the midst of older formations would overturn every inference to be derived, from their being observed to emanate from strata of a more recent date.

The legitimate deduction from the above facts are, moreover, strengthened by considering the mineralogical and chemical constitution of trachyte, both which bear such a resemblance to that of granite, that the rock has been called by Dolomieu granitoid lava.

And although the two rocks may be distinguished, by the presence of quartz in the one, and its absence from the other, yet the predominance of felspar in both seems to place them in the same genus, and to distinguish them from the constituents of secondary strata, where that mineral hardly can be said to occur, except where we have reason to suspect the agency of fire.

It is probable, too, that the chemical composition of granite and trachyte taken from the same localities, would not be found to vary materially, notwithstanding the differences in their mineral constitution pointed out.

Thus, though quartz is wanting in trachyte, and abundant in granite, yet the silicious earth contained in that mineral, may have united with the alumina present, in such proportions as would form felspar, and in this manner the latter may have become more abundant, at the expense of the other two ingredients of the granite.

In some cases, on the contrary, where the material operated upon consisted chiefly of quartz, the result may have been that variety called millstone trachyte, which, though chiefly silicious, betrays its igneous origin by the cells and cavities it so abundantly contains.

If, then, there be reason to conclude, that the substance, which has supplied the materials ejected by burning mountains, or constituting their internal nucleus, be derived from granitic rocks, a strong argument will be afforded, in favour of the great depth at which the operations are seated, that have given rise to the effects we witness.

This inference, indeed, is greatly strengthened by a consideration of the phenomena attendant on an eruption, the general tenour of which plainly denotes, that the focus of the action is situated at a depth at the least as great, as that to which granite may be supposed to extend.

We do not, indeed, lay any stress on the remarks of Stukeley, who calculates from the compass of country over which earthquakes have been felt, that the force must, in some instances, be 200 miles beneath the surface, because we have seen reason to believe, that vibrations may be propagated laterally beyond the immediate influence of the impelling force; but we would argue, from the immense mass of materials ejected by any one volcano, as for instance by Etna or Vesuvius, without exhausting itself, or causing any sinking of the mountain; from the prodigious height, to which the trachytic nucleus of others seems to be raised, as at Teneriffe and in Equinoctial America; and, lastly, from the immense violence of the eruptions, which would shiver into pieces any merely superficial covering of rock, that the elastic vapours must be disengaged at a depth at least as great, as that to which the crust of the earth can be supposed to extend.

Constitution of a Volcanic Mountain in general.

Having now examined the products of subterranean fire individually, we will next consider them in the aggregate, and explain the manner in which they produce those vast accumulations of volcanic materials, which occupy so large a portion of the surface of our Globe.

Those observers, who have been fortunate enough to obtain a near view of the crater of a burning mountain, in what is called its active condition, inform us, that the interior of it is filled with a body of melted lava, which may be seen alternately rising and falling within the chasm. At its maximum of elevation, one or more immense bubbles have been seen to form on the surface of the lava, and rapidly swelling, to explode with a loud detonation. This explosion drives upwards a shower of liquid lava, which, cooling rapidly in the air, falls in the form of scoriæ. The surface of the lava is in turn depressed, and sinks several feet, but is propelled again upwards in a moment by the rise of fresh volumes of elastic fluids, which escape in a similar manner. Such is the account given by Mr. Scrope of the crater of Stromboli, which he surveyed from a commanding point of rock; such likewise in the main is that given by Spallanzani of Etna, by Bory St. Vincent of the volcanos of the Isle of Bourbon, and by Ellis of Kirauea, in Owhyhee. In all these cases, a mass of melted matter, of unknown depth, covered for the most part with a thin pellicle of scoriform lava, and emitting copious volumes of steam or gas, was observed in the crater which they overlooked.

Now it is evident, that the tendency to eruption in all these cases will depend upon the relation existing between the expansive energy of the materials and the controlling force, derived, in part, from the pressure of the superincumbent atmosphere or ocean, and in part, from the weight of the column of liquefied matter; and as in general a considerable proportion of the matters ejected during a paroxysm of volcanic action falls back into the crater, whilst the elastic fluids, which served to expel them, escape, the active state of a volcano will in these cases be intermittent, and its eruptions placed at distant intervals asunder.

In a few rare instances, as at Stromboli, where, from some peculiarity in the configuration of the mountain, the whole of the ejected materials falls into the sea, and is carried away by a strong current to a distance, the repressive and expansive forces may be so equally balanced, that a series of explosions shall occur at short intervals, for any length of time during which the volcanic processes continue, without any accession of violence ever taking place, sufficient to produce the emission of a continuous current of lava. In cases where the opposite forces are so nicely balanced, it may happen, as Mr. Scrope has ingeniously suggested, that the mere variations of atmospheric pressure would cause a difference in the explosive force, and thus may explain what the inhabitants of that Island are said to have remarked, that the intensity of the eruptive violence is greatest in stormy weather.

Craters of Eruption.

It is evident, then, if we suppose this to be the condition of every active volcano, that, when once the violence of its operations has arrived to such a pitch, as to overcome the resistance opposed to it, the elastic vapours will throw out portions of the liquid lava, just as, when a mass of melted metal happens to fall into a vessel containing water, the steam generated disperses it in all directions. These portions of lava projected into the air, descend again in the form of scoriæ or sand, and collect into an aggregate, which is called, rather improperly perhaps, a bed of volcanic tuff.

But the projection of these fragments is soon followed by the overflow of the melted lava itself, which by degrees reaches the brim, spreads over the tuff, and forms a regular bed encircling the original aperture.

Now the repetition of these successive operations would cause just that alternation of beds of lava and tuff, which is found to constitute the sides of most volcanic craters, and it will be at once seen, that the direction in which they lie, to appearance horizontal, when viewed from the interior of the chasm, but in reality dipping on all sides away from the centre at an angle of about 30°, is exactly what would happen, if we suppose them formed in the manner represented. In plate v. fig. 9. the disposition of the beds in a crater of eruption is given, and, as contrasted with it, is shown that of the beds on a hill, which may chance to have been hollowed out by the action of water, in a manner, which causes it to correspond in external appearance with that belonging to the crater, after the latter has been broken away, and partially destroyed, by the agency of other causes.

It is true, that we can hardly imagine many hundred alternations of strata so constituted to mantle round the crater in the way supposed; for it is evident, that the slightest irregularity in the brim over which the lava flowed, or upon which the scoriæ descended, would determine these materials more on one side than the rest, so that we should never find, after the first few beds had been formed, any that actually extended round the whole circumference.

But Professor Lyell has stated from actual observation, that this appearance of uniformity is delusive, and that the cone is in reality composed of a number of beds, each of which thins out so gradually, as to be confounded, and to appear continuous, with some other placed next it.

Craters of Elevation.

The above statement of the ordinary succession of phenomena occurring during a volcanic eruption, which we owe originally to M. Neckar de Saussure, supplies us with a very simple and natural explanation of the structure of an ordinary volcanic cone, the quaquaversal dip of its strata, the regular alternation of tuff and lava, and even perhaps of the dykes which intersect them. But are we at liberty to infer, that the whole of a volcanic mountain, whatever may be its form, antiquity, or position, whether situated, like Vesuvius, on the borders of the sea, or like the Peak of Teneriffe in the midst of a fathomless ocean, is built up entirely after this fashion?

Even in the absence of any direct evidence on the subject, we should be inclined to hesitate before we adopted such a conclusion, and to ask ourselves whether, under so enormous a pressure as that of the Ocean, the expansive force of elastic fluids, struggling to escape, would not be more likely to upheave in the first place the strata nearest the focus of the action, when softened by the heat, within a given area, than to eject fragments of rock round a cone in the manner represented.

We might also feel perplexed to explain on such a supposition the appearance of any detached volcanic mountain in deep water, since such materials, if accumulated under the sea, would be too quickly diffused over its bottom, to raise the level to any considerable height at one particular point.

It would also seem, that if earthquakes are allowed to have brought about an occasional upheaving of the Earth's surface, and that, without producing such a confusion of the strata affected, as even to interfere with the springs of the country, or to throw down the buildings erected on the spot, there would be still greater reason for attributing the same effects to volcanic action exerted upon rocks which have been actually softened by the previously existing heat.

But independently of these probabilities, there are not wanting direct proofs of the upheaving of rocks, that appear to be connected in some way with volcanic operations; proofs derived, in some cases from the appearances they present, and in others from the actual testimony of eye-witnesses.

Upheaving of Volcanic Mountains shown,

First, by their own appearances.

The former are drawn from the examination of volcanic mountains, whose interior structure is from some cause or other in such a manner exposed to view, as to reveal to us the real nature of the material which composes its nucleus.

Thus in the Island of Great Canary, and still more remarkable in that of Palma, a chasm called the Caldera exists, nearly 4000 feet in depth, which afforded to Von Buch an excellent section of the internal structure of the mountain itself. Lowest of all he discovered the primitive rocks, then masses of trachyte, and above various alternations of those volcanic strata which usually occur in craters. The latter, for ought we know, may have been formed by successive ejections of lava and scoriæ; but the trachyte and the granite underneath must have been upheaved, for why else do we find them at a height, which, though 4000 feet perhaps from the summit, is at least 3000 from the base of the mountain, and consequently from the level of the sea, and that sea too unfathomable? Can we resist the belief, that at least the granite with its superincumbent trachyte were upheaved from the bottom of the Ocean by volcanic agency, and thus constituted a nucleus, round which the subsequent ejections have taken place? Ought not such an example to be regarded as more conclusive, than the observations of a contrary tendency which other Geologists have recorded, with respect to the appearances presented in some of those deep valleys, which exhibit sections of the interior of the volcano?

Where, as in the case of the Val de Bove on Mount Etna, the structure is similar to that which at present results from the eruptions, that from time to time take place, we have doubtless a right to assume that they were produced in a similar manner, and consequently the antiquity of the volcano is enhanced, in proportion to the extent of the series of strata so exposed; but we are not therefore entitled to conclude, that the original formation of the volcano must have been of the same nature with that of its subsequent growth, still less to extend the same inference to other volcanos that may appear differently constituted.

Secondly, by the Existence of Domes of Trachyte.

Of the upheaving of trachyte in detached dome-shaped or conical masses, and that by forces which we can hardly hesitate to regard as volcanic, examples, we conceive, of even a less equivocal kind, may be found, in Countries more accessible to the European traveller.

To what other cause, for example, are we to attribute the occurrence of those five isolated hills of domite, which we meet with near Clermont in Auvergne, the largest of which, the Puy de Dome, rises nearly 3000 feet above the general level of the plateau on which it rests?

On what possible supposition are we to account, for the regularity of their form, their perfectly detached position, and their occurring, each in the midst of an amphitheatre, composed of volcanic rocks of a totally different kind? Shall we imagine them to be the relics of a continuous stratum, once spreading over the adjacent country, but since removed by subsequent changes? or shall we suppose them to be masses of a kind of lava, which, from its imperfect fluidity, accumulated round a central point, without spreading into the adjacent plain? The former supposition seems irreconcilable with the fact of the total absence of all traces of the rock elsewhere, and with the conical form belonging to some of these masses; the latter is manifestly inconsistent with its chemical constitution, and the idea of its owing its fluidity to intense heat, which we have thought fit on other grounds to adopt.*

In one of these hills, the Puy Chopine, we appear even to be able to trace the very steps by which the process has taken place. We observe here, not merely a rock composed of that variety of trachyte, which in the other four hills constitutes the whole mass, but by the side of it, forming the side fronting the South-west, South-east, and East, a congeries of various primitive and volcanic rocks in different states of alteration. We may enumerate, a conglomerate of scoriæ and volcanic tuff, of basalt, hornblende slate, sienite, and granite, more or less disintegrated, especially where in contact with the trachyte. The whole of the mountain is surrounded by an amphitheatre of rocks composed of a congeries of scoriform volcanic products, from the midst of which it appears to have been elevated; so that we seem to have at once presented before our eyes, the material from which the trachyte was elaborated, the several steps in the process of change effected, and the mode in which, when so prepared, it was made to occupy its present position.

---

* See this question more fully discussed in a Letter to Professor Jameson, on the Diluvial Theory, and on the Origin of the Valleys of Auvergne, by Professor Daubeny, published in the *Edinburgh New Philosophical Journal for April*, 1831.

If, however, we believe Humboldt, the New World must present a much more decisive instance of the kind, than the Puys of Auvergne we have been just considering; since Chimborazo, the highest mountain in that hemisphere, is represented by him, as composed entirely of trachyte, and being, both in form and composition, on the great scale, what the Grand Sarcouy in Auvergne is on a smaller one.

Now we may remark, that it is only because these mountains, owing to the shifting of the volcanic fire to another quarter immediately after their elevation, or to some other peculiarity in their physical condition, have given rise to no ejections of lava or scoriæ, that we are enabled to ascertain so decisively their constitution; for had they assumed the character of permanent vents, and consequently been covered, as Etna and Vesuvius are, by a numerous succession of layers of volcanic materials, we should then have been induced to conclude, that they were entirely built up of that, which constituted in reality merely their external superficies.

There are also not wanting instances in volcanic districts, where the ordinary rocks of the country have been heaved up round a circumscribed area, evidently by the expansive force of vapours from beneath, so as to form crater-shaped cavities, resembling in all particulars, except in their component parts, that assumed by a volcano. Mr. Scrope himself has described one of them in page 74 of his *Memoir on Central France*, where he makes mention of a circular lake called Le Gour de Tazana, about half a mile in diameter, and from thirty to forty feet deep. Its margin, for a fourth of the circumference, is flat, and elevated above the valley into which the lake discharges itself. Every where else it is environed by steep granitic rocks, thickly sprinkled with small scoriæ and puzzolana, and rising about 200 feet from the level of the water. These fragments are all that indicate the volcanic origin of this gulf-like basin, but they are sufficiently decisive. No stream of lava, or even fragments, of any large size, are perceivable.

Similarly formed craters occur likewise in the Eyfel; and perhaps the best example of them is the circular volcanic lake called the Meerfeld, hollowed out of transition slate and red sandstone, without any admixture of volcanic matter, though surrounded by loose fragments of augitic lava. Now if we admit, that in these instances, the rocks in question have acquired their actual position from the operation of expansive vapours acting from below, what reason is there for questioning the possibility of the same forces having acted likewise upon volcanic strata, and caused them to be upheaved in a similar manner?

Even limestone rocks, if we believe Von Buch, have sometimes been elevated by volcanic agency in a conical form, so as to imitate in their appearance the trachytic masses mentioned as occurring in Auvergne.

Instances of this kind are met with between Trent and Roveredo, and it is remarkable, that the rock in every case is of a dolomitic character, whereas the limestones in the neighbourhood are destitute of magnesia. The same remark applies, as we have seen, to the ejected masses of granular limestone found at Vesuvius, which are dolomitic, although the apennine limestone of the neighbourhood is in general not magnesian.[*] (See pl. iv. fig. 7. 8.)

Hence Von Buch has had the boldness to attribute this latter ingredient to the volcanic action, imagining the Earth in question to have penetrated the volcanic matter whilst in a liquid or pasty condition, so as to form with it a chemical compound.

There are, it must be confessed, weighty difficulties in the way of such a supposition, and in some of the spots which Von Buch has appealed to in proof of his theory, as, for instance, at Gerolstein in the Eyfel, the circumstances are such as to preclude us from adopting such a supposition, without a manifest anachronism;[†] nevertheless the singular appearances of these rocks, and their connection with the surrounding strata, have induced many to suspend their judgment, and to regard the impregnation of limestone with magnesia, in the manner supposed, as one of those facts, which a more advanced stage of chemical knowledge may explain, or at least render more conceivable.

Even those who reject this theory of Von Buch's, will hardly hesitate to regard the curved stratification, manifested not unfrequently in our sections of the Earth's surface, as caused by an upheaving force. We are indebted to Mr. Bakewell for presenting us with an instance, which seems to comprehend all the conditions requisite for establishing this view of the case. Four miles East of Matlock, in the isolated hill called Crick Cliff, about 900 feet above the Derwent, the strata rise in all directions towards the central point, so as to form nearly spherical segments. (See pl. iv. fig. 6.)

The true structure of the hill has been discovered by recent mining operations, several valuable metallic veins having been explored in it, and a gallery driven in it, as represented in the figure.

Now it is obvious, that, although the inclination of plane strata may result from subsidence, such an arched structure as that represented could hardly have been formed except by protrusion, of which its proximity to beds of toadstone, to which we ascribe a volcanic origin, suggests an explanation. In this instance, however, we are not left to conjecture; for lately, in driving the gallery on towards the centre of the hill, a mass of toadstone was met with; and the same was found, by sinking a shaft from the top of the hill, so that the cause and the effects are at once displayed, in the section we are enabled to give of this hill.[‡]

---

[*] In fig. 7. is an ideal section by Von Buch of the rocks in the Val de Fassa, Tyrol, showing the manner in which he conceives the pyroxenic porphyry to have first heaved up and displaced the shelly limestone, together with the other rocks, and afterwards to have converted it into those masses of dolomite which cap the summits of the overhanging mountains.

In fig. 8. a drawing is given of one of these dolomitic mountains; and the position of the porphyry, the shelly limestone, and the red sandstone with reference to it, is indicated by the annexed figures

Testimony in favour of the Elevation of Volcanic Rocks.

But if the appearances which are presented by many of the rocks affected by volcanic fire lead to a conclusion favourable to the notion of their having been uplifted; still more decisive is the evidence afforded us by those persons, who have either been eye-witnesses of the formation of a volcano in a new site, or have been situated, nearest in point of time or place, to the theatre of such events.

Father Gorce, in 1707, was eye-witness of the appearance of a new rock, between the two Islands of Great and Little Cammeni, off Santorino in the Grecian Archipelago. He states, that it gradually increased in size and in height, until it became half a mile in circumference, and rose twenty or thirty feet above the level of the sea, bringing up with it live oysters. After this had happened, a crater appears to have been formed, from which fragments of volcanic matter were ejected, and the latter now cover the surface of the Island, and conceal the underlying rock.

Among the Aleutian group, Langsdorf has described a rock near the Island of Unalaschka, 3000 feet in height, consisting of trachyte, which made its appearance in 1795, and seems to have been thrown up all at once from the bottom of the Ocean. The Island that has recently appeared in the Mediterranean between Sicily and the African coast, though the part elevated above the sea was made up of scoriform matters disposed in concentric layers round a central orifice, seems below to have consisted of an upheaved mass of rock. It is certain, at least, from Captain Smyth's account, that the depth of the water on the site of the Island was at least 100 fathoms, when he sounded it in 1814; and it appears from the chart accompanying Dr. Davy's Paper, that it varies in the immediate vicinity of the Island from 1 to 12 fathoms, from whence it gradually increases, so that at a distance of from 100 to 200 yards from it, the present soundings are from 20 to 65 fathoms.

Now this change of level may no doubt be explained in two ways; either by the gradual accumulation of scoriæ and other volcanic products, or by the more sudden elevation of a portion of the bed of the Mediterranean. With either hypothesis the structure of the crater is equally compatible; for it is natural to suppose that, after a conical mass had been upheaved, ejections of scoriæ might have taken place round a central point.

But with regard to the mode in which the operations of the volcano began, we are disposed to give the preference to the hypothesis of a sudden upheaving; for to have raised the bed of the sea from 100 to 10 or 12 fathoms water, would seem to require a longer continuance of volcanic operations than is noticed as having occurred on this spot, as well as a wider dispersion of the ejected masses over the sea than appears to have been the case. We hear indeed of scoriæ and ashes having been distributed in all directions, even to the coast of Sicily, but we do not find any sensible difference in the level of the sea recorded, excepting within an area of one or two hundred yards round the Island, from which central point, therefore, the sea appears to sink abruptly in every direction.

Phenomena of Jorullo.

Lastly, Humboldt has presented us with an instance, where, in the centre of the great table land of Mexico, and at a period not more distant than the middle of the last Century, both the descriptions given by the inhabitants of the country, who were actual eye-witnesses of the event, and the appearances exhibited at the time the spot was visited by himself, led him to the conclusion, that a large tract of ground from three to four square miles in extent was heaved up in a convex form to the height of 550 feet, and that from the midst of this protuberance arose six conical hills, the least of them 300 feet in height, and the loftiest, Jorullo, elevated 1600 feet above the level of the plain.

Certain English Geologists have lately questioned the soundness of this explanation, and have suggested that the convexity of the plain may have been produced by a simultaneous overflow of lava from the six cones, and that these, uniting into one sheet, may have formed a sort of circular pool or lake of lava.

But this solution seems to us clogged with still greater difficulties than that offered by Humboldt; for although it be true, that the viscidity of a lava current is such, that we ought not to suppose it subjected altogether to the same laws as those which regulate the flowing of a body of water, still it seems probable, that some trifling inequality of surface in the plain over which it has spread, some variation in the quantity of lava given out from the different orifices, would determine the sheet of lava to one point rather than to another, and thus produce a stream flowing in a given direction, instead of a lake of melted matter circumscribed within so definite an area.

It has been said, indeed, that the heaving up of a tract of land of this kind is unprecedented; but so, it may be replied, is the formation of such a convexity, by the mere overflow of a stream of lava proceeding from any existing volcano. And it must moreover be recollected, that, according to the very conditions of the theory advocated by those Geologists who have objected to Humboldt's views on this point, our historical records would embrace so very small a portion of the time occupied by any of the great physical revolutions of our Globe, that there appears the less reason, for circumscribing Geological reasoning strictly to the data obtained by actual observation, provided it assumes nothing inconsistent with the laws which the latter tend to establish.

Thus we have literally no record of any other volcano formed in a new site upon land, than this of Jorullo; for the throwing up of the Monte Nuovo near Naples can be regarded in no other light, than as a transference of the volcanic action, which is taking place at the Solfatara, or at Vesuvius, to another neighbouring quarter.

It may also be remarked, that the existence of a hollow space beneath a volcano, which may be accounted for, although it does not necessarily follow, from the uplifting of the rocks composing its nucleus, seems the best and most obvious means of explaining the phenomenon stated by Dr. Horsfield to have occurred in Java; where the mountain Papendayang, formerly one of the largest volcanos in the Island, is said to have given way, and in part to have fallen in, so that an extent of ground, fifteen miles long and six broad, was swallowed up in the bowels of the earth, with the destruction of forty villages and a large proportion of their inhabitants.

There seems, therefore, good reason to believe, that volcanic rocks have been heaved up, both in the sea and on land, by the expansive force of elastic vapours, a position of greater importance in a theoretical point of view than might be at first anticipated, seeing, that it justifies us in applying these same forces to the explanation of the more extensive elevations of mountain ranges, of which Geology apprizes us, though, as of the elevation of cones of trachyte, history is silent concerning them. Now a belief in the elevation of isolated masses of rock may serve to reconcile us to certain opinions, with respect to the origin of volcanic craters, which, resting as they do on the authority of the two individuals, who have examined volcanos, on the most extensive scale, and under the greatest variety of aspects, deserve from us at least a patient and unprejudiced hearing.

Craters of Elevation.

Von Buch has distinguished the craters of volcanos into two classes: those produced by eruption, and by elevation. The former are brought about in the manner already pointed out by Neckar de Saussure and others, and are found in all volcanos which have given rise to currents of lava, or have constituted permanent vents of volcanic materials.

The latter are produced, owing to the upheaving of the crust of the Earth by the agency of elastic vapours round a certain limited area, and may, therefore, consist either of the older rocks of the country, or of the products that have been accumulated by antecedent volcanic operations. The one may be illustrated by the crater of Meerfield in the Eyfel, and that of the Tour de Gazana in Auvergne; of the latter (the Puy de Dôme) and other conical masses of trachyte afford, as we conceive, unexceptionable examples.

Now as the structure of a crater of eruption has been compared by Professor Lyell to that of an exogenous tree, which increases by layers deposited from without; so that of a crater of elevation may, to follow up the same analogy, be perhaps compared to that of an endogenous one, where the growth is caused by the protrusion of a mass from within. The question, therefore, is, in what way are we to determine whether a given crater, or, to speak more generally, a given volcanic formation, be the result of the one or of the other process?

And here we must refer to an excellent Memoir lately published by Messrs. Elie de Bourmont and Dufrenoy, who adopt the following method of distinguishing between the two.

When the sides of the mountain are covered with bands of lava circumscribed within narrow limits, we may fairly infer that they have been formed by successive ejections; when, on the contrary, the whole circumference of the cone is covered by a continuous sheet of volcanic matter, which is commonly the case where the substance of it is basaltic or compact, we may presume that it has once been nearly horizontal, and has since become upraised. The former may happen most commonly in those volcanos which are subaerial and at present in action, but the latter is the case generally in those which are subaqueous.

If we suppose a body of liquid lava to be ejected from the bottom of a deep sea, and consequently under the pressure of a considerable volume of water, a crust would quickly form over its upper surface, in consequence of the rapid abstraction of heat by the water immediately superincumbent; so that the lava subsequently ejected would be compelled, by the resistance opposed by this hard, unyielding mass to its progress upwards, to spread itself laterally in all directions; thus forming a sheet or tabular mass of lava extending over the bottom of the sea on which it was poured out.*

Now it is evident, that an explosion of gas taking place underneath a mass of lava, such as that represented, might produce a crater of elevation, by heaving up the lava round a given area, and producing a central cavity, through which the elastic vapours and solid matters ejected might continue to escape.

Messrs. Elie de Beaumont and Dufrenoy appeal to the elevated table lands of Mont Dor and Cantal, as affording instances of elevation, but as being altogether irreconcilable with the doctrine of craters of eruption; and it is certain, that if the sheets of trachyte are really continuous, we will not say over the whole of these mountains, but over any considerable portion of them, the notion of their being caused by successive ejections from a number of distinct craters, must be renounced as untenable. M. Virlet, indeed, one of the most distinguished opponents of the elevation theory in France, who accompanied the scientific expedition sent by the French Government to the Morea, is compelled to admit, that the eruptions, which built up the Mont Dor and the Cantal, must have been on a greater scale than any which we at present experience; thus giving up the very point which pleads most strongly in favour of the rival theory, by admitting, that causes now in action, operating with only their present intensity, are inadequate to produce the phenomena. On the other hand, the adversaries of Von Buch's theory in this Country, more consistent in their opposition, endeavour to show, that lava currents of equal extent have been produced in modern days; and doubtless Iceland, and even Sicily, afford examples, which may be fairly brought into competition with those of more ancient date.

But Messrs. de Beaumont and Dufrenoy contend, with great appearance of justice, that it is only when the lava has reached a tract of nearly level land, that it spreads itself over so wide a surface as is there represented, and that during its descent down the sides of the volcano it is almost invariably circumscribed within a very limited area.

When, therefore, we observe a conical hill composed of sheets of lava or trachyte, which can be ascertained to be continuous round the whole or the greater part of its circumference, we must suppose it once to have been horizontal, and afterwards to have been heaved up into its existing position.

Von Buch has, however, extended his theory to such craters as that of the Islands of Palma and of the Great Canary, assuming that all the strata observed in looking down from the summit of the Caldera have been upheaved, and that this deep chasm has been formed in consequence.

The Caldera of the Isle of Palma, says Von Buch, differs from a crater of eruption in many striking particulars. Here are no streams of lava, no slags, no lapilli, or ashes. Nor do we ever find the latter of such a circumference, or so profound and abrupt. Its general aspect seems to show, that it was formed by the pressure of those elastic fluids, which raised the whole Island above the level of the Ocean, and changed the strata composing it from an horizontal to their present highly inclined position. The aspect of those narrow and precipitous ravines, called Barancos, which encircle it, favours this hypothesis. They are so circumstanced, that we can hardly attribute them to the action of water; but if we suppose a succession of solid and unelastic strata to be suddenly lifted up in the manner of those in the Island of Palma, it is evident that not only would a central aperture be formed where the crater now exists, but that the strain would occasion a number of lateral fissures, corresponding with those called in the Island Barancos.

---

* See Delabeche's *Manual*, third edition, p. 125.

To those, indeed, who have hitherto derived their notions on these subjects exclusively from English sources, we would recommend the perusal of the great Work on the Canary Islands, which we owe to the Prussian Geologist above mentioned. We shall there find a record of phenomena, which seem hardly reconcilable to that theory with regard to the building up of volcanic mountains by the successive ejections of beds of scoriæ and lava, which, from its seductive simplicity, is calculated in a manner to preoccupy the mind of the Geologist.

We shall there see whole islands formed, of beds of basalt, not of scoriæ or of tuff, preserving in their external circumference a circular form nearly as perfect as that of the brim of their central crater, towards which they on all sides incline. We shall then see, in the midst of this amphitheatre, of basaltic rocks, and of other materials, which could scarcely have been formed excepting under water, a conical mass of trachyte rising to a great height with a crater in its centre,* and this crater one, which has not in all cases emitted lava currents or scoriæ, but has served only as a vent for steam or gases. Now, if these appearances can be best explained by an upheaving of rocks previously formed beneath the bed of the Ocean, what arguments of a general nature can be alleged to prevent us from adopting such a conclusion, seeing, that we are only extending to the materials of a whole island, what all admit with respect to certain isolated rocks; imagining that to have taken place in Palma, and the Great Canary, which we have almost been eye-witnesses of at the Islands of Santorino and Sciacca; proceeding, as it appears to us, legitimately, from the observed consequences of earthquakes at present, to the inferred effects of similar forces at periods antecedent?

That the hypothesis in question may have been pushed too far, and that some of the followers of Von Buch, originally misled by his authority, may have since been obliged to retrace their steps, is nowise improbable; but this does not invalidate the truth of the facts, which he and others have alleged, as applicable to the cases of Teneriffe, or Jorullo, or oblige us to imagine all volcanos, in whatever quarter of the Globe they may be, to be built up, after the model of those few on the borders of the Mediterranean, which chance to be most accessible to Europeans.

We hold, in short, that it would be just as illogical to argue, that because many craters have been built up by the gradual accumulation of successive eruptions, therefore that the same must have been the case with all, as to contend, that because the trachyte which forms the bottom of the Caldera has been uplifted, therefore that the strata superimposed upon it must have been so likewise, without reference to their nature or contents.

Both descriptions of crater probably have a real existence in nature, and the business of the Geologist, therefore, is to distinguish the one from the other, by a particular examination of each, and by considering, whether the strata that compose it have most the appearance of submarine lavas, or of those products, which are seen forming under our eyes by subaerial volcanos.

We have been disposed to dwell the more upon this theory of Von Buch, conceiving that justice has hardly been done to its pretensions by English Geologists, partly, in consequence of the original papers, in which his views were promulgated, having never been translated into our language, and partly, in consequence of their being somewhat at variance with certain doctrines in this Science, prevalent at the present time amongst us.

If, however, we may presume to act as arbiters between this great German Geologist, and his opponents in England, we should say, that the latter are perfectly justified in referring to processes of which they have daily experience, those craters to which both theories may be applicable, on the very same principle, on which we have ourselves given a preference to the simpler hypothesis advanced by Professor Forbes, and since so ably advocated by Mr. Lyell, to account for the phenomena of the Temple at Puzzuoli, (see p. 717.) though we have seen nothing to convince us, that the more complicated theory advanced by Goethe would not likewise account for them. On this principle we do not doubt that Hoffman has done right in retracting his original opinion with respect to Mount Etna being a crater of elevation, though we have yet to learn that this concession on his part ought to be construed into a general abandonment of Von Buch's theory as applied to other cases. On the other hand we would submit to our readers, whether, on reviewing the facts that have been put before them, they will not conclude, that the objections raised against the possibility of such cases occurring, as Von Buch has exemplified in his Work on the Canary Islands, rest on too narrow a view of volcanic phenomena, which, in order to be complete and satisfactory, ought to embrace the phenomena observed in Equinoctial America, as well as those of Europe; the extinct volcanos of Auvergne, as well as the recent ones of Naples and Sicily; and which, at least, should admit of being applied to all cases of upheaving, whether occurring in primary ranges of mountains, in the so called valleys of elevation existing amongst newer deposits, or in tracts of confessedly igneous origin.

SECTION 4.
Theory of Volcanic Operations.

Having now treated in succession the different phenomena found to accompany volcanic action in its various phases of intensity, we may, perhaps, be in some degree prepared to estimate the relative probability of the two modes already mentioned, by which its existence has been accounted for.

We say, the relative probability of the two, for after all, there will be few so wedded to either, as not to contemplate, new volcanic phenomena being brought to light, fresh principles in Chemistry becoming recognised, which may give a preference to some third explanation, entirely different from either of the foregoing, seeing, that one of those conditions laid down by Lord Bacon as requisite in order to guarantee our belief in a theory, namely, that the cause assigned should be ascertained to have a real existence, can be predicated neither of the one nor of the other.

We would also remark, that the real question at issue between the advocates of the rival theories, stated in its broadest terms, is simply this;—whether the phenomena of volcanos seem to imply a process of oxydation or not; if they do, then our acquaintance with bodies which are kindled by the mere contact of water, enables us to explain the manner in which the process of combustion may originate, its continuance becoming a matter of subsequent consideration; whilst, if the facts before us can be accounted for merely by assuming the presence in the interior of the Globe of a mass of melted matter, we should scarcely be disposed to go further for a solution of them.

---

* The drawing of the cone and crater of Barren Island, Bay of Bengal, pl. iv. fig. 4. will give some idea of what is here described.

Now the progressive refrigeration of a ball of melted matter proceeding from its circumference towards its centre, would doubtless produce something like an imitation of one volcanic phenomenon, namely the emission of lava currents, since the contraction of the crust upon its internal contents would squeeze out from to time, at the points of least resistance, a portion of liquid matter proportionate to the gradual diminution of its capacity.

We may also understand, why the points of least resistance should often be on the coasts or in the depressed portions of continents; why the action of the volcano should in general be intermittent; and why it should continue for centuries without becoming exhausted.

We might also account on this hypothesis for the volumes of carbonic acid emitted, regarding them as resulting from the action of the heat upon the constituents of the limestone rocks placed within the sphere of its operation, and consequently as being unconnected with any process of combustion.

But, on the other hand, this hypothesis does not explain, why volcanos should break out in the middle of the sea, where the pressure must be greater, than it is on continents, intersected as the latter are with caverns and fissures; why it should take place in certain lines of coast only, and not generally, wherever there be low land; and why, fed as they would be from an inexhaustible fountain of liquid matter, they should ever become extinguished, or, at least, continue dormant for no very extended a period, as to convey to us that impression.

Neither does this hypothesis explain the differences that exist between the products of volcanos, which, if derived from the same internal source, ought perhaps to be uniform in their composition and structure.

In conceding, therefore, that the conditions of this hypothesis permit us to explain this phenomenon, it is conceived, that we have gone further than we are strictly warranted in doing; whilst with regard to others more characteristic and essential than even the emission of lava, it leaves us altogether in the dark.

In what manner, for example, will the admission of Cordier's theory enable us to account for the evolution of steam, and of the different gases, which we have seen to be constantly present, or for the consequences of the confinement of these elastic fluids in the interior of the Earth, which manifest themselves, in the explosions that accompany an eruption, or in the upheaving of rocks and the production of earthquakes which we attribute to its operations?

Nor can we be considered guilty of any gratuitous assumption in thus attributing them; for, although the upheaving effects of volcanic action have been by some ascribed merely to the hydrostatic pressure of a mass of lava, which had been forced up to the summit of the crater, yet it is plain, that to have brought it into that position in defiance of the laws of gravity, some powerfully moving force must have been required, and what force can be suggested, at once so probable in itself, and so adequate to the effect brought about, as the evolution of a great body of elastic vapour, the existence of which we are compelled from many other considerations to admit?

Aware probably of the difficulties that suggest themselves to Cordier's theory in this its most simple form, many of those who profess to support it, call into play another principle, namely the action of water, which, making its way to depths where the Earth is supposed to maintain a temperature sufficiently exalted for this purpose, is converted into steam, and thus serves by its elastic force to eject the various heated matters which issue from the orifice.

It must be confessed, that such an addition to the theory supplies us with an explanation of much, which former view of it had overlooked, especially, the situation of volcanos near the sea, their power of upheaving rocks, and in general the expansive force, which constitutes one of their leading features.

Yet even here, unless we suppose some kind of combustion to take place, we are left in the dark, with regard to the evolution of sulphurous acid and of nitrogen gases; and unless we suppose the existence of some principle or other capable of decomposing, as well as of converting into vapour, the water that finds admission, we shall hardly be able to account for the steady and copious emission of hydrogen combined with sulphur, which has been noticed.

It may, indeed, be said, that sulphurous acid would arise from the spontaneous union of sulphur with oxygen, at the high temperature to which it would be subjected, if it existed so deep in the bowels of the Earth; and that several of the commoner metals, such as iron, are capable of decomposing water, and combining with the oxygen of the atmosphere, when subjected to the same heat—whence would result an evolution, both of sulphuretted hydrogen, and of the residuary nitrogen, derived from the atmospheric air admitted.

But when the naturalist is once brought to allow, that combustion of some kind or other makes a part of volcanic operations, he will necessarily look to the products of these latter, in order to satisfy himself, what the materials may have been which have contributed to the effects.

Now we have already seen, that the substances ejected from the crater of a volcano usually consist, in the largest proportion of silex, next of alumina, then of oxide of iron, then lime, and lastly soda or potass.

That the elements of these bodies must, some of them at least, have absorbed oxygen from the atmosphere, during the process by which their fusion has been effected, seems to follow, from the nitrogen disengaged, and the ammoniacal salts sublimed; and if we are thus brought to admit, that a metal so oxidizable as iron may exist in its metallic condition at these depths, what is to hinder us from going one step further, and applying the same supposition to the bases of the earths, and alkalies, thus obtaining a readier solution of the energetic character of those processes, which are adequate to produce the effects we witness?

It has, indeed, been alleged, that the two principal constituents of lava, namely, the bases of silica and alumina, are not highly inflammable. Silicon, when perfectly pure, resists a white heat without uniting with oxygen, and aluminium may be boiled in water without decomposing it. But, in the first place, it is rare to meet with these oxides, without finding them accompanied either with lime or an alkali; and the basis of the former, we have reason, from Davy's experiments, to believe, is highly inflammable; the latter we know to be so.

Secondly, silicon kindles readily if united with a little hydrogen or with carbonate of soda; and aluminium even by itself burns brilliantly when heated to redness, and dissolves with the evolution of hydrogen in very dilute solutions of potass.

There is, therefore, no difficulty in imagining the combustion to be kept up by means of the silicon and aluminium, when once it has been commenced by the action of water, upon the potassium, sodium, or calcium present.

It has also been objected, that hydrogen gas is never emitted from the spiracles of any volcano, as if it were not quite natural, that it should be evolved in union with sulphur, when generated in places so abounding in that material.

That the quantity thus emitted has been enormous, will appear from this consideration alone, namely, that the immense beds of sulphur in Sicily are probably derived from certain submarine solfataras, and that in solfataras the sulphur which is deposited arises, not from the sublimation of that solid, but from the deposition of it by the sulphuretted hydrogen and sulphurous acid disengaged, which, when they come into contact, mutually decompose each other.

It is not clear, also, that hydrogen gas may not be evolved likewise in combination with carbon, and even with phosphorus, since the flame, which has been represented as rising from the ground both during earthquakes and volcanic eruptions, indicates the former; and the bubbling up of gas, through the sea, which inflamed on coming into contact with the air, a phenomenon observed near the Azores, would seem to imply the latter.

At all events, a large proportion of the hydrogen emitted may be presumed to make its appearance in the ammoniacal salts disengaged, and a still larger proportion to be recombined with the oxygen of the atmospheric air present, and to appear as steam.

The above hypothesis has this further recommendation—that it accounts for the intense action, which appears to be kept up in some cases without intermission for a considerable period, although it must be supposed to be taking place in caverns, or confined spaces deep in the bowels of the earth.

Had the combustion been of such a nature, as to give rise only to some gaseous product, such as carbonic acid, the combustion would soon have been suspended, or at least checked, by the predominance of a principle so destructive to flame, as we find to be the case in coal mines that have caught fire. Nor would the result have been different, if sulphur, or even phosphorus, had been the sole materials by which the combustion was maintained, for in either instance an atmosphere would have been produced, in which the further oxydation of these bodies could not have proceeded.

But, supposing the substances inflamed to be metals, which form with oxygen a fixed product, and disengage from water an inflammable principle, as in the case assumed, we can see no reason, why the combustion might not continue for ages with unabated vigour, as is the case in several volcanos.

An objection against our hypothesis has also been sometimes deduced from the mean density of the Earth, which is calculated at five times that of water; and hence it has been concluded, that bodies so light, as potassium and sodium are, cannot make a part of its nucleus.

But we are not obliged to imagine a larger proportion of these alkaline bases to be present, than would be implied by the composition of the lava emitted, and probably we shall find not more than four or five per cent. of potass or soda to exist in the average of volcanic productions.

On the other hand, the specific gravity of the basis of silica, and, probably, also, of that of the other earths which predominate in lava, is sufficiently considerable to warrant the conclusion, that a mass of matter, containing these principles in the proportions indicated, and united with as much metallic iron, as we know to exist in the state of an oxide in the generality of lavas, would form an aggregate possessing an higher specific gravity, than that of the compound resulting from the oxydation of the entire mass.

Let us take, for instance, the analysis given by Dr. Kennedy of the lava from Etna, which he states to consist of

Silica	52	per cent.	× Sp. gr. 2.65	= 127.8
Alumina...	19	per cent.	× Sp. gr. 4.20	= 79.8
Lime......	10	per cent.	× Sp. gr. 3.00	= 30.0
Oxide of iron	15	per cent.	× Sp. gr. 5.00	= 75.0
Soda......	4	per cent.	× Sp. gr. 2.00	= 8.0
	100			320.6

We here find that 100 parts of this lava have a specific gravity equal to 320.6, and consequently that the specific gravity of the mass would be no more than 3.2, supposing it divested of water.

Now let us contrast this with the specific gravity of 100 parts of the metallic principles, which would give rise to a mineral possessing the above chemical composition.

Silica.....	52	contains of base	26	× Sp. gr. 2.0	= 52.0
Alumina ..	19	contains of base	10	× Sp. gr. 2.0	= 20.0
Lime	10	contains of base	7	× Sp. gr. 4.0	= 28.0
Oxide of iron	15	contains of base	12	× Sp. gr. 7.8	= 93.6
Soda.....	4	contains of base	3	× Sp. gr. 1.0	= 3.0
	100		58		196.6

Now as 58 — 196 — 100 — 340.

Consequently the specific gravity of the whole would be no less than 3.4. The specific gravity of aluminium appears not to be ascertained, but probably it is not inferior to that of silicon, which sinks in the strongest sulphuric acid, and therefore is more than 1.83.

The theory, therefore, we have been advocating, leaves the question with respect to the cause of the Earth's density just on the same footing as before. Those who are of opinion, that the latter may be explained by the mere condensation of such rocks as are found near the surface, in consequence of the superincumbent weight, as certain metals may be rendered heavier by pressure, are entitled to extend this explanation to the case of the alkaline and earthy bases; whilst those who regard the density of the Earth to be a proof, that some heavier matter must exist below, are not precluded from such a supposition, as our theory implies merely the existence of such a quantity of metallic ingredients, as would be sufficient to produce the materials ejected, leaving the constitution of the remainder just as open to conjecture as it was before.

It is curious, indeed, that whilst some have argued, that the kind of materials found near the surface is inadequate to account for the density attributed to the Earth in general; others, as the late distinguished Professor Leslie, have contended, that these substances would have their specific gravity so much increased by the enormous pressure, that void internal spaces must be necessarily supposed. On this he has founded his singular hypothesis, that the centre of the Earth is filled only with light, the rarest substance known; an idea, the mere mention of which is sufficient to show, how little we can be justified in rejecting an explanation of facts, merely because it appears to militate against the conjectures, that may be conjured up with regard to the internal condition of our Planet.

Dismissing, therefore, this objection, and leaving to our readers full liberty to form their own conclusions with respect to the internal state of the Globe, granting even to such as contend for it, that an internal fluid mass might give rise to some of the phenomena of volcanos; we conceive, that if the opposite theory can explain other effects, which the above leaves untouched, in addition to those which it elucidates, we are bound by every rule of sound reasoning to allow it the preference.

Now that this is the case, we shall attempt to show, by deducing, from the supposed existence of the alkaline and earthy metalloids at a certain depth in the Earth, the several phenomena of volcanos, in the order in which they present themselves.

Statement of the Theory proposed.

We will suppose, that the nucleus of the Earth, at a depth of three or four miles, either consists of, or contains as a constituent part, combinations of the alkaline and earthy metalloids, as well as of iron and other more common metals, in the proportions indicated by the composition of lava; these being combined, perhaps, with sulphur, and constituting various sulpho-salts. Such bodies are gradually undergoing decomposition, wherever they come into contact with air and water, but, defended by the crust of the Globe, as even a mass of potassium of a certain size may be by a crust of its own oxide, if kept perfectly dry, the chemical action excited goes on too slowly to produce any of its more striking effects, unless the latter of these agents be present in considerable quantity. Hence, under our continents, the elastic fluids generated, and the heat evolved, show themselves principally, in their influence on the temperature of the interior, or in the phenomena of thermal waters.

But under the sea, or in any other situation where the pressure of an equally large column of superincumbent fluid assists in forcing the water though the crevices of the subjacent rocks, the action must often go on more rapidly, and the effects consequently wear a more formidable aspect.

These latter, however, will occur in the middle of the sea less generally than on the coast, because the pressure of the Ocean itself furnishes an impediment to the escape of elastic fluids, greater than that of the contiguous land, and they will in general not be constant but intermittent, because the heat generated by the process itself will have a tendency to close the orifice by which the water entered, first, by injecting the fluid lava into the fissure, and secondly, by causing a general expansion of the rock; nor will the water again find admission, until, owing to the cessation of the process, the rock becomes cool, and consequently again contracts nearly to its original dimensions.

Now the first effect of the action of water upon the alkaline and earthy metalloids would be, the production of a large volume of hydrogen, which will either combine with oxygen (supposing atmospheric air to be present) or with sulphur, both being at the high temperature favourable to their union. In the former case, nitrogen gas will be given off, and this, expanded by the heat, will rise towards the surface, either in its free state, or combined with a portion of the hydrogen in the form of ammonia, which, however, will be neutralized by the free muriatic acid, the strongest usually present. Hence the sal ammoniac, so frequently found in volcanos, and the nitrogen given off in hot springs.

The hydrogen not thus disposed of, combining with the sulphur, will form sulphuretted hydrogen gas, which, for the same reason, will rise upwards in a gaseous form, unless it be decomposed by union with oxygen, or in any other way.

But so long as oxygen be present, in sufficient quantity to combine with the hydrogen, and re-convert it into water, the sulphur will continue in combustion, and consequently sulphurous acid will be predominant amongst the gaseous exhalations emitted from the mouth of the volcano.

So soon, however, as the oxygen is consumed, the hydrogen, no longer entering into combustion, unites with the heated sulphur, and escapes in the form of sulphuretted hydrogen, which consequently, towards the close of the eruption, when the oxygen is expended, will predominate.

As, however, the two gases alluded to mutually decompose each other, the appearance of sulphuretted hydrogen from the mouth indicates, not necessarily the entire absence of sulphurous acid at the place where the process is going on, but its less copious production than before, owing to the more scanty supply of oxygen.

The very circumstance of the reproduction of water, by the mutual decomposition of these two gases, might be the means of keeping up the action in a languid manner for an indefinite period.

The slowness with which lava cools, would cause it to go on giving out, for a considerable time, sufficient heat to the adjoining strata, to communicate to the sulphur the temperature necessary to occasion its combination with oxygen; hence, a certain portion of sulphurous acid would be continually emitted, which, however, would be soon decomposed by the hepatic gas present. The water resulting from this process would percolate into the recesses of the rock, attack any portions of the alkaline and earthy metalloids that might have escaped the original action, and give birth to a fresh volume of hydrogen gas, ready in its turn to dissolve a new portion of sulphur, and thereby to contribute to a repetition of the same phenomena. Thus, no diminution in the quantity of water present on the surface of the Globe need arise from even an endless repetition of volcanic processes, a comparatively small portion of that fluid fulfilling the same office in these great natural laboratories, which a little nitre discharges in an oil of vitriol manufactory; the same water serving over and over again as the carrier of oxygen to whatever metallic matter is capable of decomposing it, just as the nitrous gas generated by the nitre furnishes oxygen to the sulphurous acid, owing to its previous conversion into nitrous acid vapour.

The separation of muriatic acid from the common salt and other muriates present in sea water, is explained on the common principles of chemistry, by the superior affinity exerted by the alkaline base at these high temperatures for the silicious or aluminous earth than for the acid; and the sublimation of iron, in the state of *fer oligiste*, a protoxide, rather than in that of a peroxide, may have resulted from the deoxydizing property of the sulphuretted hydrogen, at the same time disengaged.

The carbonic acid is probably derived from the action of the heat on the calcareous strata contiguous, and is consequently given off even by volcanos that appear extinct, owing to the long continuance of the heat, or the languid action going on long after the tendency to eruption has ceased.

All the phenomena, in short, which are concomitant upon volcanic action, seem to admit of explanation, if we will only suppose salt-water, and afterwards atmospheric air, to find admittance to cavities in the interior of the Earth, where they can come into contact with the metals, and the earthy or alkaline metalloids, combined with sulphur, there existing; and if it be objected, that the presence of air in the interior of a volcano, in sufficient quantity, seems problematical, we may reply, that as the first effect of the heat would be to produce a softening of the contiguous strata, it must necessarily happen, that the evolution of so large a portion of elastic matter would have the effect of bearing them up to a certain distance round the focus of the volcanic action.

This aperture would undoubtedly be occupied in the first instance by the gases given off by the volcano itself; but the slightest intermittence, or even inequality in the process, would occasion a partial vacuum, which the air of the atmosphere would immediately fill.

We may fortify these conclusions by the authority of Sir H. Davy, who in a *Memoir on the Phenomena of Volcanos*, published in the *Philosophical Transactions for* 1828, remarks, that there was every reason to suppose in Vesuvius the existence of a descending current of air; that the subterranean thunder heard at such great distances underneath the mountain, is almost a demonstration of the existence of great cavities below, filled with aeriform matter; and that the same excavations, which in the active state of the volcano throw out during so great a length of time immense volumes of steam, must, there is every reason to believe, in its quiet state, become filled with atmospheric air.

Hence, perhaps, we may explain a phenomenon that has been noticed during the continuance of an eruption, namely, that of the air being heard to rush through the various spiracles of the mountain, with a loud, and as it is represented, an almost musical sound.

Notwithstanding, therefore, the respect we entertain for the authorities, both in this Country and on the Continent, which, in discussing these two theories, appear to have thrown their weight into the opposite scale, we are still disposed to prefer the chemical one just laid down, to that which, in contradistinction to it, we shall venture to denominate the mechanical one.

Not one of the supporters of the latter view has, so far as our information extends, attempted to do that, which alone can exalt an hypothesis, from the rank of a mere vague suggestion of the fancy, to that of a rational and satisfactory solution of a physical problem: none of them has undertaken the task of taking up, one after the other, the phenomena that have been observed to occur during the different stages of volcanic agency, and showing their respective agreement with the principle laid down at the commencement.

This we have at least endeavoured to accomplish in the foregoing pages; and until the same shall have been effected by the advocates of the rival theory, we must be excused for adopting that view, which, even if less simple, we are at least entitled to consider for the present more adequate to embrace all the conditions of the problem to be solved.

Neither should it be forgotten by those who object to our views, on the ground that the existence of the metallic bases of the earths and alkalies in the interior of the Globe is imaginary, that so likewise is that of their own fundamental postulate—the mass of melted matter in the interior of the Globe which they assume; whilst the high temperature belonging to the crust of the Earth, wherever it is out of reach of atmospheric changes, so far from affording any independent proof of their position, would be an almost necessary consequence of such chemical processes as those in which we suppose volcanic action to originate.

PART II.

DESCRIPTION OF ROCKS, ATTRIBUTED TO VOLCANIC ACTION TAKING PLACE UNDER CIRCUMSTANCES DIFFERENT FROM THOSE BEFORE CONSIDERED.

Section 1.

On Trap Rocks.

Introduction.

Having now concluded our intended sketch of the phenomena of existing volcanos, and attempted to explain the causes from which they originate, we have to consider in the next place, the influence which they may have exerted on the condition of our Planet, the rocks that have been produced by their operations, or altered in character and position by their agency.

It is this part of the inquiry, which connects the subject of volcanos with the other investigations of Geology, and renders their study of interest, not merely to the Chemist and the Natural Philosopher, but likewise to all who would attempt to explain the condition, past or present, of the Globe we inhabit.

We shall begin then, by considering the rocks, which, though differing in some respects from those produced by volcanos at the present day, appear to us, nevertheless, to be derived from the same cause acting under somewhat altered circumstances.

There are few parts of the World, that do not offer examples of those rocks, which are comprehended by Geologists under the name of trap, including, as it does in its most extensive signification, on the one hand, basalts, greenstones, syenites, and wacke, and on the other, porphyries with base of felspar or claystone. To each of these general subdivisions are annexed sundry mechanical aggregates, in which pebbles or angular fragments of the rocks above mentioned constitute the prevailing ingredients.

Basalt

The first of these, basalt, appears to be an intimate mixture of compact felspar, either with hornblende, with augite, or with both. It is sometimes of an uniform texture, but more commonly contains imbedded crystals of olivine, augite, felspar, and titaniferous iron ore.

Its decomposition seems to give rise to the substance called wacke, a rock of a dull earthy appearance, and a dark greenish or reddish colour, which, when it admits of being examined, appears to be composed of augite or hornblende, with felspar, altered from the effects of weathering or other causes.

Greenstone.

The rock called greenstone is a granular aggregate of those minerals, which in basalt are so intimately mixed, as to be undistinguishable by the naked eye. It, therefore, consists essentially of felspar, either with augite or with hornblende, but the predominance of one or other of the two latter minerals over the felspar, communicates to the general mass that greenish colour from which its name is derived. Thus the term hornblende includes both the rock denominated diabase, and that called dolerite, by Brongniart; it may also comprehend, in a Geological sense, the hypersthene rocks noticed by Dr. Macculloch in Sky, and other parts of Scotland, where the mineral called hypersthene takes the place of the augite or hornblende which generally belongs to it.

Syenite.

Syenite differs from greenstone rather in the proportion, than in the nature of the minerals that compose it.

It consists essentially of felspar and hornblende, but the greater predominance of felspar imparts to the mass a lighter colour. Quartz is also a frequent ingredient, and mica sometimes occurs imbedded.

Claystone Porphyry.

Syenite, therefore, forms the connecting link between this class of trap rocks and the second, where the basis is either of felspar or claystone, which latter is probably only a more earthy and disintegrated condition of the former mineral, bearing the same relation to compact felspar, which wacke appears to do to basalt. The crystals, which impart to this rock its porphyritic character, are necessarily of felspar, but others are often imbedded, such as quartz, mica, augite, or hornblende. Where the basis is claystone, the rock is called claystone porphyry; where it consists of compact felspar, the name of felspar porphyry is applied to it.

In other cases, it consists of that slaty and splintery species of felspar, denominated clinkstone, and then is usually known by the name of clinkstone porphyry.

More rarely the porphyritic structure is not discernible, in which case the rock is called simply, claystone, compact felspar, or clinkstone, according to the nature of its constitution.

With this, or the foregoing class, are sometimes associated other rocks, which appear, from the analogy of their structure and chemical composition, to have been formed by similar natural processes.

Such are the hypersthene rocks above noticed; and to this same denomination appear to belong the serpentine rocks which occur in primitive, transition, and even in secondary formations. Serpentine seems to consist of an intimate mixture of the mineral termed diallage, with felspar; and, when it occurs in a granular condition, constitutes the gabbro of the Italians, or the euphotide of Brongniart. It, therefore, bears the same relation to the latter, which basalt does to greenstone.

Pitchstone.

Another rock belonging to this series is pitchstone, which either consists wholly of the mineral so denominated, or of a basis of that mineral with crystals of glassy felspar, by which it is rendered porphyritic.

It may, perhaps, be considered, rather as a particular form or condition of felspar or basalt, than as a distinct substance, holding to these minerals a relation similar to that which obsidian does to lava.

There ought, therefore, to be two species of pitchstone, the one associated with basaltic, the other with felspathic traps, but the rock commonly so denominated appears to be allied to the latter.

The above-mentioned rocks are found in two different conditions, distinguished by the presence or absence of cells and cavities; the former may be denominated compact, the latter vesicular; terms, which include the corresponding states in which modern volcanic products also occur. Vesicular traps, however, are almost invariably found with their cavities more or less completely filled up with various crystalline minerals, especially calcareous spar, quartz, the several members of the zeolite family, green earth, &c.; hence they are denominated amygdaloids, a term which, in some Geological Treatises, is used to designate a distinct rock, but which in reality constitutes only a particular state, in which all the rocks of the trap family are occasionally found.

Thus we have, amygdaloidal basalt, amygdaloidal greenstone, amygdaloidal wacke, and, though more rarely, amygdaloidal porphyries.

They are also found in fragments or rolled masses, imbedded in a basis consisting of the earthy variety of basaltic or felspathic trap; in other words, either in wacke or in claystone. These mechanical aggregates are known under the generic name of tuff, being called trap-tuff, when the basis is of wacke, and claystone-tuff when it consists of claystone.

Both of them bear a close analogy to the volcanic tuffs, but differ generally in the degree of their aggregation from the latter, the basis of which, being for the most part a kind of volcanic sand, possesses a looser degree of consistency than that which accompanies trap rocks.

General Characters of the foregoing Rocks.

The above rocks have this peculiarity belonging to them, that they occur in connection with all the formations enumerated in the former part of this Treatise, from the oldest to the most modern, resting on them in irregular tabular masses, occasionally alternating with, and still more commonly intersecting them at various angles.

When circumstanced in either of the two former ways with reference to the accompanying strata, they have been denominated beds, with what propriety will afterwards appear; when disposed in the latter way they are called trap veins or whin dykes; whin being a provincial term, originally employed by the colliers in Northumberland to designate any hard stone, but now introduced into the general language of Geology, for the purpose of indicating a rock, consisting of basalt, greenstone, or wacke, traversing the strata in the manner that has been represented.

We shall consider, in the first place, the general structure of trap rocks, and afterwards, those circumstances which may be regarded as peculiar, either to the one, or other of the forms in which it is found.

Trap rocks, in some one of their different forms, present examples probably of every kind of structure which has elsewhere been observed: examined on the small scale, we remark them amygdaloidal, porphyritic, and granular; examined on the large, we find them in some instances slaty or fissile, as clinkstone, in others divided into thick tabular masses, as basalt and greenstone frequently are.

Prismatic Structure.

But that which peculiarly distinguishes rocks of the trap family, is the tendency to split into prismatic, or, speaking more generally, polyedral masses, which, though it exists likewise in granitic and a few other species of rocks, is no where so frequent or so well displayed as in these. The columns vary in the number of their sides from three, to six, seven, and even twelve; they are more generally straight, but not unfrequently curved; in size they may be said to vary, from an inch to nine feet in breadth, and from a foot to 300 or more in height. They are sometimes continuous for a considerable space, but at other times are obliquely and irregularly divided by fissures or joints, the convex surface of the one being inserted into a corresponding concavity of the other.

The columns are usually at right angles to the direction of the bed, but not always so; in some instances, indeed, they radiate from a central point, forming clusters of columns without any determinate direction, and still more commonly they are placed so irregularly as to interfere one with the other. Sometimes in the same bed, one portion will be prismatic and the rest amorphous, whilst every intermediate condition, from that of jointed columns possessing an almost architectural regularity, to a total absence of all arrangement, will be perceived.

It has been usual to refer this kind of structure to the contraction, which the mass underwent during its cooling down from a melted state; and there is no doubt, that a prismatic structure may arise from a cause of this kind, as we see exemplified in many modern lavas, and in the shrinking of masses of clay, starch, &c.

But there is one circumstance which seems to prove, that the prismatic form of trap is owing to a different cause; namely, that in many cases the columns approximate so nearly, that not even the blade of a knife can be thrust in between them. Now in every instance in which the same kind of structure is produced by contraction, theory suggests, and experience confirms, the conclusion, that a certain interval would be left between the columnar masses so produced.

Spheroidal Structure.

We must, therefore, look to some other cause for the columnar arrangement of trap, and probably the true solution will be afforded us, by considering another kind of structure noticed as existing in these rocks, namely, the spheroidal or globular. In this kind of structure, the rock is either wholly or in part arranged in balls of various magnitudes. The globular form is very conspicuous in the rock of the Shiant Islands; but according to Dr. Macculloch does not appear to be common. A tendency, however, to this structure is manifested in most trap rocks, by the manner in which they disintegrate, those even which are columnar exfoliating into spheroidal forms when exposed to the weather. Now, it is evident, that a series of globular concretions of trap, placed in close contact, whilst in a pasty condition, or in the state of transition from fusion to solidity, would be by mutual pressure converted into a succession of jointed columns, which, owing to slight differences in the compactness and consequent softness of the several parts of the mass, would rarely be exact in their sizes and in the number of their sides, but would exhibit all those variations, which, in that respect, columnar basalt commonly displays. Neither does it follow, that they may not in some cases have shrunk, after the prismatic form has been communicated to them by mutual compression, since this would begin to operate from the moment they ceased to be liquid; whereas the tendency to contract would continue up to the time at which the rock had sunk to the temperature of the bodies surrounding it.

We conceive, therefore, that the spheroidal structure will be found to be the one most prevalent in rocks of the trap family, and that the prismatic is in general only a consequence of it; the former, indeed, arising from a kind of molecular attraction, which begins to display itself in all melted bodies, from the moment they cease to be absolutely fluid, up to the time at which they become completely solid. Hence, the longer the interval between these two points, the more fully does this disposition operate, as has been shown by Mr. Gregory Watt and others, who have caused the particles of glass, and even of lava, to arrange themselves in spheroidal concretions, by allowing them, after being melted, to return to a state of solidity with sufficient slowness.

Having now considered the general structure of trap rocks, let us next examine the peculiarities belonging to either of the two conditions in which they exist.

Tabular Masses of Trap.

One of the most common forms in which the harder varieties of trap are found, is in large overlying masses, sometimes rising into high mountains, but more generally capping the summits of hills of comparatively low elevation. These latter sometimes would seem to indicate stratification, but this appearance is owing to their division into large tabular masses, which again have a tendency to decompose, in an abrupt manner, at right angles to the seams of the stratification, thus presenting a series of mural precipices, ranging one above the other, from which the term trap, which, in Swedish, signifies a *stair*, has been applied to them.

In other cases they appear to alternate with the rocks of the country, but this appearance is most frequently, though not always, deceptive. Dr. Macculloch has shown, that many veins of trap put on a form so far parallel to the stratification, as, when partially viewed, to possess the semblance of beds. Their true nature may in these cases be determined by finding that the parallelism is not long maintained, but that any one such supposed stratum quits its place to intersect the adjoining and including stratified rock, or sends ramifications through the whole series. (See plate v. fig. 6.)

In a few cases, where deep sections of cliffs afford opportunities for examination, it is found, that irregular masses lie beneath the stratified rocks in some places, just as they surmount them in others; and that, from these also, veins proceed to the surface, or in other directions.

Without, therefore, altogether denying, that alternations of trap rocks with neptunian deposits may occur, a consequence which would necessarily ensue, if successive formations of the former rock had taken place at the bottom of water, which was at the time in the act of producing deposits of clay, limestone, or sand; let us go on to consider the case of veins or dykes, to which class the great majority probably of stratiform masses of trap actually belong.

Dykes of Trap.

These dykes occur of all sizes, from a few inches to twenty or thirty yards in thickness. They extend in some cases many miles in length, as in the case of the great Cleaveland dyke in the North of England, which has been traced in a direct line more than seventy miles. They seldom ramify, but pursue their primary direction in one continuous line. They are usually intersected by fissures at right angles to their walls, and are thus divided into irregularly prismatic concretions.

They often penetrate rocks belonging to different epochs, and wherever the circumstances of the country allow us to follow them for any distance, have been found connected with some great mass of the same material. From their superior hardness and durability, they generally resist decomposition better than the rocks which they intersect, and consequently stand out above the surface of the ground, like walls of stone, whence, indeed, they are termed dykes: the term wall and dyke being synonymous in North Britain. Their effects upon the contiguous rocks are very remarkable. The latter are often thrown down on one side, and elevated on the other, as if by the forcible intrusion of the trap. The same thing occurs, when two trap dykes cross one another, that which has been shifted being considered as of the greatest antiquity. The contiguous rock is variously altered according to its mineral constitution, If it be limestone, it is often rendered hard and crystalline, like marble; if shale or slate clay, it is turned into a substance resembling flinty slate or porcelain jasper; if sandstone, it is rendered hard, and, in a few cases, prismatic; if it be gneiss, it is converted into a kind of hornstone. (Nigg near Aberdeen.)

But the most striking alteration is observed, where the dyke intersects the coal strata. In some cases (Cleaveland) the substance of the coal in immediate contact with the trap is converted into soot, whilst at a little distance it is reduced to a coke or cinder, wholly destitute of bitumen. The roof immediately over the coal is lined with crystals of sulphur, which may have been sublimed from the coal.

Nevertheless these effects do not appear to be universal, and it sometimes happens, that a dyke will traverse a series of rocks for a vast distance, without in the least affecting them. They are also much more commonly produced by dykes, than by overlying masses of trap, though the case of the Meisner shows, that a similar influence is sometimes exerted even by a bed of greenstone overlying coal.

Origin of Trap Rocks.

Such then are the principal facts that seem agreed upon, with respect to the composition, structure, and position of trap rocks; and the conclusion, to which the greater part of them evidently point, is, that they have been produced by igneous action of a kind similar to that, by which volcanic products are forming at the present day.

Their chemical constitution can hardly be held consistent with any other supposition, for they have been found by Kennedy to agree very nearly in this respect with those volcanic products, which they most resemble mineralogically, consisting, like the latter, of compounds of silica, with alumine, lime, and an alkali, commonly potass; substances, which have been never known to enter into chemical union, except under the influence of a high temperature, and have not yet been found as parts of any neptunian deposit, except as rolled masses derived from another quarter.

The general correspondence in mineralogical character, which may be traced betwixt trap and volcanic rocks, is still more conclusive. Thus the basalts of the one find their analogues amongst the augitic lavas of the other; the syenites and greenstones correspond with the greystones or tephrines, and the claystone and felspar porphyry with the trachytes that accompany modern volcanos. We even discover occasionally, in the midst of the products of volcanos, that have been in action since the valleys of the country were excavated, and, therefore, at a recent period, rocks so nearly identical in characters to those which usually are considered as trap, that we cannot deny that the latter are, in fact, produced by volcanic processes. Of this kind are the basaltic colonnades, which occupy the bottom of the valleys in the Vivarais, and have evidently been derived from the volcanic craters above them. The mineralogical and chemical composition, as well as the prismatic structure, of these basalts, are precisely the same as those met with in trap districts; the only distinction that can be perceived being, the presence of void cells or cavities of very minute size, which seldom exist in the older traps without being occupied more or less with crystalline matter.

Neither would it be difficult to find, among the trachytes of Hungary, Auvergne, or the Euganean hills, rocks identical in structure and composition with the porphyries of older date; as, for example, those which accompany the trap rocks at Sandy Brae, in the County of Antrim. The inferences too which an examination of the rocks, placed as it were at the opposite extremities of the series in point of antiquity, could not fail to suggest, are greatly confirmed, by observing the appearances presented by those which belong to an intermediate age. From whatever cause it may have arisen, it is at least certain, that, connected with the deposits belonging to the tertiary periods, is found a class of rocks, which, if regarded as volcanic, seem often to present the characters of trap; and if considered as trap, to put on frequently the characters of recent volcanic products. Such are the formations in the Val di Noto, in Sicily, in several parts of Italy, in Auvergne, in Hungary, and in other parts of Europe, all of which have been traced to one particular period in the history of our Planet; namely, one subsequent to that at which the chalk appears to have been deposited, but antecedent to that in which the Earth was peopled by its present inhabitants.

Nothing, it is clear, could afford a more striking proof of an identity in the origin of trap and volcanic rocks, than this apparent transition from one to the other, in proportion as the circumstances under which they were formed came more and more to resemble those of the present time.

Wernerian Theory with regard to Trap.

Yet, notwithstanding this accumulation of evidence in favour of the community of their origin, it is no long time since the opposite opinion was espoused by some of the most distinguished Geologists in Europe, and a theory, at once clumsy and gratuitous, was invented, for the purpose of explaining, without having recourse to igneous agency, the position occupied by trap rocks, which lie incumbent on whatever stratum might chance to be uppermost.

No doubt, the weight attached to the name of Werner, who was regarded not unjustly as the father of scientific Geology, gave to his views on this subject a currency, which they would not othewise have obtained, but even his authority would not have induced his disciples so generally to adopt his opinion, had there not been difficulties in the way of the opposite doctrine, which served in some degree as a set-off to the glaring absurdities of their own. We ought indeed, in candour, to suppose, that the Neptunians, as they were called, agreed only in rejecting the volcanic theory of trap as supported by insufficient evidence, and that the majority of them entertained no very decided views with regard to the manner in which it was really formed. Werner, indeed, had called up the ocean to the very summits of the hills, at a period subsequent to the deposition of the other rocks, in order to overspread the Earth with the materials of his newest flœtz trap formation; but his followers must have regarded this merely in the light of an hypothesis, brought forward in order to show, that other possible modes of accounting for the origin of trap might be imagined, without invoking the aid of the God of Fire.

We shall not, therefore, concern ourselves with this hypothesis, to which few probably ever attached implicit confidence, but will merely consider, what was the nature of those difficulties, that induced so respectable a class of Geologists, not very long ago, to withhold their assent from the position, that trap rocks were the volcanic products of an earlier period. In doing this, we shall particularly refer to one only of these rocks, namely, to basalt, conceiving the whole question, as to the formation of other members of the series, to hinge entirely upon the result of our inquiry with respect to this.

Arguments in favour of the Aqueous Origin of Basalt.

The aqueous origin of basalt was asserted, or rather, to speak more correctly, its igneous origin was denied, partly from its relations to other rocks, and partly from its own composition, structure, and position.

It was shown to pass, on the one hand into greenstone, and on the other into wacke, both which substances, it was argued, must have been of aqueous origin; greenstone, because, if it had undergone fusion, the crystals found in it would have been obliterated; wacke, on account of its passage into clay and similar confessedly neptunian deposits.

It was also found to alternate repeatedly with these latter, often without effecting any apparent change in their nature.

The composition of basalt, it was said, contradicts the idea of its having been affected by fire;—it contains water, which does not exist, as had been shown by Kennedy, in the recent lavas most nearly allied to it—it contains various crystals which are fusible at a heat below that at which basalt melts—and it even envelopes masses of limestone, containing all their carbonic acid, and occasionally with their petrifactions uninjured. The structure of basalt is, it was alleged, still more strongly opposed to such an opinion; instead of being vesicular, harsh, and vitreous, like modern lavas, it was compact, stony, and sonorous like iron; instead of being split into irregular, polyedral masses, with wide, intervening spaces, it was often divided into prisms affecting a great degree of regularity, and closely touching each other.

Unlike lavas, it cannot be traced to a crater; nor does it, like them, descend into the bottoms of valleys; but is found often capping hills, whilst it is entirely absent from the low country contiguous.

As to the similarity between basalts and lavas in point of chemical composition, it was argued, that this only proved the latter to have been derived from the fusion of trap, not the former to have been produced by heat themselves.

Shown to be fallacious.

Some of these arguments, no doubt, were founded on a mistaken representation of facts: thus wacke being an earthy kind of trap, and containing the same ingredients as basalt, may be produced in some instances from the disintegration of the latter rock; and when that is the case, its further decomposition would give rise to a rock no wise different from clay. All the cases, probably, in which the passage from basalt to clay has been asserted, fall under this predicament.

The greater number, too, of the cases cited, in which organic remains are said to have been detected in trap, are equally erroneous: the rock in which they are found, being either a trap tuff, as in the Island of Canna; or a wacke, derived, probably, from the decomposition of basalt, as at Joachimstal, in Saxony; or, lastly, a rock altered by the contact of basalt, as the flinty slate of Portrush, near the Giant's Causeway, which contains ammonites.

But, even if basalt had in any instance been found to contain organic remains, this would be no more than has been met with among the ejections of volcanos. Thus, as Mr. Delabeche informs us, in Signor Monticelli's collection of Vesuvian products at Naples, occur fragments of the compact limestones of the district with their organic remains imbedded.

The presence of crystals fusible at a heat below that required by their matrix, offers no objection to the igneous origin of trap, now that it is conceded, that these very crystals may have been produced subsequently, owing to the play of affinities brought about by the fusion of the mass, and operating during the progress of its return to a state of solidity.

Differences between Lava and Basalt explained.

But there are other manifest differences between basalts and lavas, which require to be accounted for, before we allow ourselves to refer the former to volcanic agency; namely, their greater compactness and more stony aspect, the general absence of glassy and of vesicular products, the more regular prismatic structure which they assume, their originating in dykes, and not in craters, and other peculiarities above alluded to.

It remains then to be seen, what were the conditions, which caused the volcanic products of an earlier period to assume an appearance in many respects so different from that which they affect at present.

One circumstance will immediately occur to us, as establishing a distinction between the two cases.

We have seen in the former part of this Treatise, that up to the period of the tertiary formations, the greater part of the Globe, or at least of that portion of it which has come under our observation, was covered to a great depth by water; for, although the formation of beds of coal, the occasional occurrence of fresh water shells, and that of the remains of land animals, convince us, that certain portions of what is now dry land was even at that time elevated above the waters: still it is probable, that these constituted merely detached Islands in the midst of the abyss of ocean; and that the great bulk of our continents were at that period submerged. It follows from this, that the majority of the trap rocks then formed must have been submarine lavas, and hence we see at once a distinction between the above and those of the present day, which, wherever they are presented to our observation, are necessarily subaereal, or at least consolidated only in shallow water. Thus in the volcanic Island recently produced in the Mediterranean, the products that have come under our notice, are porous and vitreous, like those of Vesuvius; but these, though products of a submarine volcano, have all been ejected into the open air, and, consequently, partake of the character of subaereal lavas.

Effects of Heat modified by Pressure.

This distinction, first pointed out by Dolomieu and Strange, was happily applied by Dr. Hutton, in his celebrated Theory of the Earth, to account for the differences between trap rocks and lavas, on the principle, that the effect of the heat applied would be modified in these two cases, by the influence of the pressure exercised by a superincumbent ocean upon the former, and by the absence of any such pressure on the latter.

"The tendency of an increased pressure," to use the words of his illustrator, Professor Playfair, "on the bodies to which heat was applied, is to restrain the volatility of those parts which otherwise would make their escape, and to force them to endure a more intense action of heat. At a certain depth under the sea, therefore, the power of a very intense heat might be unable to drive off the oily or bituminous parts from the inflammable matter there deposited; so that, when the heat was withdrawn, these principles might be found still united to the earthy and carbonic parts, forming a substance very unlike the residuum obtained after combustion under a pressure no greater than that of the atmosphere. It is in like manner reasonable to believe, that on the application of heat to calcareous bodies under great compression, the carbonic acid would be forced to remain, the generation of quicklime would be prevented, and the whole might be softened, or even completely melted; which last effect, though not deducible from any experiment yet made, is rendered very possible from the analogy of certain phenomena."

These latter anticipations were soon after realized by the masterly experiments undertaken by Sir James Hall, which showed, that the carbonic acid, usually driven off from limestone by the action of heat, may be retained in combination with it by a pressure greatly inferior to that of the present ocean; and that the calcareous matter under such circumstances enters into fusion at a temperature, which it completely resists when this elastic material is expelled.

Sir James Hall has applied this discovery with great success to the explanation of the calcareous matter occurring in the cavities of amygdaloidal traps, and the water present in those of certain agates existing in the same class of rocks. The same will also account for the greater cellularity which modern lavas possess than the generality of traps, the former, even in the innermost part of the stream, where, owing to the pressure of the superincumbent mass, their density will be greatest, exhibiting a number of minute vesicles, the existence of which serves to distinguish them from ordinary basalt.

Not that we must suppose all trap rocks to be destitute of cells, any more than we are warranted in inferring, that all the eruptions that took place at these periods necessarily occurred in deep water.

The existence of amygdaloids, such as are the toadstones of Derbyshire, seems to imply, that the pressure under which certain traps were formed was not sufficient to prevent the disengagement of aeriform fluids; for it is difficult to reconcile this phenomenon to the theory of Sir James Hall, who imagined that such cavities were caused by the infiltration of the crystalline matter, which, when it entered into fusion with the whinstone, kept separate from it, as oil does from water. If this had been the cause of the cavities, they ought to be entirely filled with crystalline matter, which is not the case. Neither is the presence of crystalline matter occupying the cavities a fact absolutely without exceptions. Dr. Macculloch instances the trap of Little Cumbray, in the Kyles of Bute, as consisting of vesicular lava, so light as almost to float on water, having its cells entirely empty, and with a glazed, internal surface, like that of volcanic scoriæ.

But these partial exceptions will not be considered as sufficient to invalidate the general position, that traps are of submarine origin, until some Geologist will either undertake to explain, on some other principle, the differences allowed to subsist between them and lavas, or will point out the inadequacy of Sir James Hall's theory to account for these points of distinction.

Why submarine Lavas cool slowly.

It is true, that the stony aspect of basalt, and the crystalline or granular appearance belonging to greenstone and other members of the trap formation, are less obvious consequences of the principle therein assumed. But it will not be difficult to show, that, although a body of shallow water, from the more rapid cooling it would occasion, was likely to favour the formation of vitreous products even more remarkably, than that exposure to the atmosphere which subaereal lavas undergo; yet deep water would possess the opposite tendency so completely, that we ought to meet among submarine lavas few substances of this description, except where the material had been injected in thin streams into the fissures of a rock, possessing a different temperature, and therefore capable of robbing it of its heat in a more rapid manner.

In order to understand this, we need only recollect, that the cooling agency of water under ordinary circumstances, is owing, not to its being a good conductor of caloric, but to the circulation induced in the strata of that fluid when heat is applied to it.

This circulation is effected in two ways: in some degree, by the heated particles of water at bottom becoming specifically lighter, and consequently displacing those above, but in a still greater degree, owing to the absorption and subsequent disengagement of caloric, caused by the conversion of successive portions of water into steam, and their return to their original condition, when they come into contact with the supernatant liquor.

Now it seems almost a corollary from the laws established by Sir James Hall, and others, that at the bottom of the ocean none of the water could be converted into steam; for if, as this writer infers, the pressure was sufficient to preserve water existing in the very midst of the lava (where the heat must be supposed to be at its maximum) in a liquid form, still more completely would it prevent that, which was incumbent on the heated mass, from assuming a gaseous condition in consequence of the heat communicated from below. It seems probable, therefore, that, as water is in itself a slow conductor of heat, the cooling of submarine lavas ought to proceed still more leisurely than that of subaereal ones is found to do, and hence that their component parts would remain for a still longer time in that intermediate condition between fluidity and solidity, during which, as Mr. Gregory Watt and others have satisfactorily shown, the particles, released from the controlling power of cohesive attraction, and yet brought within distances favourable to the play of their mutual affinities, enter most readily into new combinations, and assume those crystalline arrangements which are natural to them.

Perhaps, likewise, the superior density of submarine lavas, the general absence of cells, and their not sending forth to the same extent those emanations of gaseous matter which appear to proceed from modern currents, might contribute to the same effect by still further prolonging the period of cooling.

Prismatic Structure accounted for.

The same considerations may explain the prismatic structure belonging to many traps, which we have shown to have resulted from the tendency to form spheroidal concretions, naturally assumed by such rocks on being allowed to cool slowly. Instances of this same structure are stated to occur amongst modern volcanic formations; as by Mr. Scrope, in the interior of the crater of Vesuvius, as displayed in 1822; and by Breislac and others, in the lower portions of a lava bed at Torre del Greco. It is certain, however, that such cases are rare, and that those igneous rocks of recent origin, in which an approach to such a structure is observable, appear for the most part to have derived it rather from the contraction occasioned by sudden cooling, than from the mutual pressure of spheroidal concretions taking place during a more gradual one.

Such are the columns of lava worked into millstones at Niedermennig, near Andernach, which manifest their real origin by gradually approximating more and more, until at a certain depth they become united into one continuous mass. Such also are the rude columns observed near Torre del Greco, belonging to a bed of lava that had flowed into the sea, the result evidently of the rapid cooling thereby occasioned; and in another instance from the same locality, in which, as Professor Lyell observes, "the rock may rather be said to be divided into numerous perpendicular fissures, than to be prismatic, although the same picturesque effect is produced. In the lava currents of Central France, (those of the Vivarais in particular,) the uppermost portion, often forty feet or more in thickness, is an amorphous mass passing downwards into lava, irregularly prismatic; and under this, there is a foundation of regular and vertical columns, in that part of the current which must have cooled most slowly. But the lavas last mentioned are often one hundred feet or more in thickness, and we cannot expect to discover the same phenomenon in the shallow currents of Vesuvius, although it may be looked for in modern streams in Iceland, which exceed even those of ancient France in volume."

Now the greater frequency of prismatic rocks in submarine than in subaereal volcanos is explained, by reflecting, that the slow cooling essential to that structure, which in the latter is accidentally, or in a few cases, brought about by the remarkable thickness of the mass superincumbent, and that only in the lower portions of the bed, is caused in the former throughout, by the vast pressure of the ocean above, whatever may be the supposed thickness of the bed itself.

Greater frequency of Dykes.

With regard to the next point to be considered, namely, the absence of craters, and the greater frequency of dykes in trap rocks, it must be admitted, that we are rather unfavourably circumstanced in order to draw a correct comparison between these and more recent volcanic products in the latter particulars. The craters of submarine volcanos, when composed of loose fragments, would be exactly the portions most likely to have been swept away by the currents of the ocean, or other causes; whilst if they consisted of lavas, they might indeed remain, and yet all vestiges of their original configuration be obliterated by the rocks superimposed.

It would be rash therefore to assert, that craters never have existed, because we do not discover any traces of them at present. On the other hand, it is only where accidental circumstances reveal to us the internal structure of a modern volcano, that we can expect to find dykes, and there we do occasionally meet with them. Thus they are well known to exist on the sides of the old crater of Monte Somma, (see pl. v. fig. 5.) and Professor Lyell has noticed the same in that of Vesuvius at present; these, however, are probably produced by the filling up of open fissures with liquid lava, which had occupied the hollow of the crater, and therefore do not precisely resemble in the mode of their formation those trap dykes which exist in older rocks, the results of an injection of liquid lava into the fissures, through which it made its escape to the surface.

In order fairly to compare together the action of ancient and modern volcanos in this respect, we ought to refer to sections of some modern volcanic mountain, taken at a distance from its crater, of which some of the Lipari Islands afford us good examples, (see Daubeny's *Descriptions of Volcanos*, and pl. v. fig. 1 and 2,) as also does the Val de Bove in Etna, described by Professor Lyell. (See pl. v. fig. 3 and 4.)

There we shall see dykes, which, though mineralogically resembling modern lavas, correspond, in their relation to the contiguous rocks, to the trap dykes described by Dr. Macculloch in his *Western Islands*, as running for a considerable space parallel to the strata, though originating in some great mass of trap underneath. (See pl. v. fig. 6.)

Nevertheless, although it is impossible by a direct appeal to facts to establish beyond the reach of cavil the greater frequency of dykes amongst submarine volcanos, yet probability is certainly in favour of such an assumption.

"If volcanic forces," remarks Professor Sedgwick, "ever have acted on a great scale upon unbroken and nearly horizontal strata, especially while such strata were under the pressure of the sea, the formation of tabular and vertical masses of lava appears a natural consequence of such action. Where, on the contrary, the pressure of the sea is removed, and the crust of the earth is broken through, volcanic fluids will find a ready escape, eruptions of lava will be confined to one spot, and the operations will be of a class altogether different." (Sedgwick's *Geol. of High Teesdale*)

Trap Rocks, at what Periods formed.

The admission, that trap rocks are lavas, tends very much to enlarge our ideas with respect to the extent of volcanic action at different periods.

From the occurrence of these products in connection with every secondary formation, from the earliest down to the most recent, the chalk, it might be concluded, that volcanic action had taken place during every one of these successive periods; but, except when they can be proved to stand in the relation of beds interposed between the strata, such an inference would not be warranted.

Let us take, for example, the oldest rock with which any considerable mass of trap is associated in Great Britain, namely, the carboniferous system of the Northern Counties, and that in the neighbourhood of Glasgow and Edinburgh.

The former of these, namely the coal field of Northumberland, is associated with many very remarkable dykes, overlying masses, and apparent beds of trap, but the most considerable of the latter, the great whin-sill, which is seen arranged conformably with the carboniferous limestone of Teesdale, and the Northern limestones of Northumberland, has been pronounced by Professor Sedgwick to be in fact a stupendous dyke, or collection of dykes, which has been injected laterally between the strata. He, however, is inclined to refer the injection of this, as well as of the majority of the trap rocks of that neighbourhood, to a period antecedent to the magnesian limestone. Mr. Hutton, and Mr. Phillips of York, differ from the professor in their view of the origin of the whin-sill, regarding it as in great measure formed by periodical submarine eruptions of lava, which took place at intervals during the deposition of the carboniferous strata with which it is associated. In either case, therefore, much of this extensive basaltic formation is allowed to be of a date as ancient as the carboniferous rocks themselves.

The trap rocks of Staffordshire, on the contrary, constitute overlying masses, which may either be contemporaneous with the coal measures on which they rest, or may have been of a date much posterior.

Lastly, the trap rocks near Glasgow are so connected with those of the Western Islands, as the latter again are with those of the County of Antrim, which are posterior to the chalk, that we should be led to assign a much later epoch to their ejection, and likewise, perhaps, to extend the same inference to those in the vicinity of Edinburgh.

Thus we have three cases brought together, in which trap rocks are associated with the same system of rocks; the one of which is of a date antecedent to the magnesian limestone, or at latest contemporaneous with it, the third of the same age as the chalk, and the second doubtful.

In Derbyshire we meet with an apparent alternation of beds of trap called toadstone, which are more generally amygdaloidal, but occasionally compact, with the carboniferous limestone formation. But before we absolutely decided that the two are contemporaneous, it would be necessary to establish more completely than has yet been done, that they are conformable. If this be not the case, they may have been ejected long subsequently.

The most extensive, however, and in all respects the most interesting system of trap rocks, found within the compass of the United Kingdom, is that which occurs in the Western Islands of Scotland, and which appears to be continued on in the County of Antrim, in Ireland. It is interesting, not only from the numerous sections which its situation near the coast supplies, but likewise from the circumstance, that it is not mixed up, as those in other instances are, with the volcanic rocks of an intermediate period, no remnant of the operations which occasioned it being discoverable, either by the existence of hot springs, emanations of carbonic acid, or even earthquakes of any remarkable kind in the contiguous country.

It affords us, therefore, the means of comparing the products of submarine volcanos with those of subaereal ones, and at the same time of inferring, on evidence as conclusive, perhaps, as the subject itself can ever admit of being adduced, that volcanic action has in some instances expended itself, or at least has periods of rest beyond comparison longer in some cases than in others. Now either of these suppositions seems more consistent with the chemical theory, which imagines a definite quantity of combustible materials to be present in particular situations, than with the opposite one, which conceives the existence of an unexhausted fountain of melted matter underneath, such as should either gush out continually, or at least flow at intervals more approaching to regularity.

The trap rocks of the Hebrides manifest themselves under all the forms which have before been alluded to; but it would seem from the observations of Macculloch and others, that the apparent alternations which have been remarked between them and the rocks of the country, are merely caused by dykes intruded laterally between the fissures of the strata. Hence we are only sure, that a considerable part at least of these trap rocks is posterior to the most recent of the strata found associated with them, and the latter appear from the researches of Mr. Murchison to belong to the oolitic series.

But there is no evidence, that they may not be much later; for the basalts of the Giant's Causeway, on the opposite coast of Ireland, intersect the chalk, and are, therefore, posterior to that formation.

It is true, that Dr. Macculloch has shown, from the occurrence of trap nodules in a conglomerate rock of Kerrera, that trap rocks must have been formed at a much earlier period; (*Western Islands*, vol. i. p. 114;) but, as we cannot on any supposition refer the whole to this epoch, we are quite at liberty to adopt any inferences, to which the facts may appear to lead, with respect to the age of the principal portion of that found in the Hebrides.

Perhaps, therefore, the Wernerians were not altogether wrong, in referring the great overlying masses of trap, that they observed in Saxony and elsewhere, to one epoch, and that the most recent, which, in the then existing state of their ignorance with respect to tertiary rocks, they were able to recognise, designating them by the name of the newest flœtz trap formation; for although we may be compelled to acknowledge, that these rocks are of several distinct periods, and that in a great majority of cases their date is uncertain, still it seems by no means improbable, that the most extensive eruptions of submarine volcanos took place about the period just alluded to.

This is rendered more agreeable to analogy, when we remark, that by far the most extensive manifestations of volcanic agency appear to have occurred, either at a period contemporaneous with that to which we have supposed the trap rocks to belong, or at one immediately subsequent to it, that is, during the deposition of the different tertiary formations.

It is remarkable, at least, that all the extinct, as well as all the active volcanos, which have been as yet explored, may be traced up to this period, regarding, that is, as we have a right to do, all the volcanic rocks of a district as emanating from the same focus of action.

Thus the lavas of the Val di Noto alternate with rocks which appear to be tertiary; as also do those of Auvergne, of Hungary, of Styria, and of the North of Italy; so that, whether we regard the trap rocks of the Hebrides as contemporaneous with the latter, and attribute their greater compactness to the depth of water under which they were ejected, and from which they may have since been upraised, or whether we prefer to consider them as produced somewhat earlier, still we shall find equal reason for concluding, that during the period comprised between the date of the deposition of the chalk, and that of the creation of the existing races of animals, circumstances were peculiarly favourable to the developement of volcanic operations.

It is remarkable, too, that trachyte, properly so called, seems almost confined to this intermediate period; for although Humboldt speaks doubtfully as to the position of this rock in the New World, yet in the Old, it is found in a number of instances posterior to some of the tertiary rocks, and we know of no instance in which it is decidedly proved to be of greater antiquity, whilst its rarity amongst lavas of modern ejection would seem to show, that it was not, under ordinary circumstances, a product of existing volcanos. Whether this circumstance is to be regarded as the *cause* or the *effect* of that elevation of a large portion of our continents from the sea, which took place at this epoch, it may be difficult to say; but it is certain, that both events may be traced to nearly the same period; and hence we observe amongst the volcanic rocks of this age, that singular intermixture of compact with cellular, of glassy with lithoid lavas, which, at the same time that it affords the most decisive evidence of the igneous origin of trap, indicates the different circumstances under which these rocks were formed; sometimes under the pressure of water, and at other times elevated above it.

SECTION 2.

On Granitic Rocks.

Various conditions of the production of igneous rocks.

The circumstances under which the germs of igneous energy may be excited to activity, are so various, that even amongst volcanic products poured into the atmosphere, there is great local diversity. If we remember that, for the most part, the phenomena of submarine volcanic action are wholly concealed from our view, we shall be prepared to expect that among the masses formerly produced by it beneath the bed of the sea, and uplifted by subsequent convulsions to the day, many varieties of rocks should be met with, differing very greatly from the products of actual volcanos. As the far greater portion of volcanic effects takes place in the deep parts of the earth, where the rocks remain to be again and again exposed to new influences, it is reasonable to suppose that the products collected from volcanic vents form but a small part of the series.

The subterranean lavas, now in course of production and consolidation, could they be uplifted to the day, would be found very different from the superficial lavas, and far more extensive and abundant. Though, as the preceding section has shown, there be many close analogies between ancient and modern igneous rocks, we ought to expect that the most abundant of these old rocks, while they afford sufficient evidence of their being generated by heat, should appear different from ordinary lava. Granitic rocks are exactly in this case; they are far more abundant than the trap rocks, which most closely imitate volcanic products, and have a different general character. Yet as between superficial and subterranean lava every variety of products may be expected to occur, corresponding to the various conditions, we find between granitic and basaltic rocks so many intermediate varieties, that it is impossible to separate by hard and decisive characters these extremes of the series of old igneous rocks. Basalt is really a volcanic product, in the restricted sense of the word, though not exclusively so; and thus we have from vesicular pumice and glassy obsidian an uninterrupted series of gradually changing aggregations to granite.

Rocks allied to granite.

Granite deviates on the one hand by continual decrease of the magnitude of its particles into very close-grained felspathic rocks, which are greatly analogous to certain kinds of porphyry; on the other, by the substitution of hornblende for mica into syenite. As examples of the latter change, we may instance the syenitic granites of Cruachan and Strontian: the former is illustrated in the granite veins of Arran, and in the fine grained granite of Wastdale and Dufton Pike. (Westmoreland.) In some cases it might, perhaps, be safely admitted, that the same originally fluid mass has been consolidated partly into granite and partly into porphyry, according to the circumstances in which the lapidification happened. In the Valteline granite deviates into hypersthene rock.

General argument.

It would be a mere waste of time to repeat, for the particular case of granite, those arguments, derived from the crystalline aggregation of many minerals never known to be produced from water, but several of which have been fabricated in the furnace, and nearly all are volcanic products, which establish the probability of the igneous origin of the whole class of plutonic rocks. We have shown above that the composition of granite passes by very easy steps to that of rocks whose igneous origin is perfectly unquestionable; if to this we add the fact, of granite entering cracks and fissures in contiguous rocks, as clay slate in Cornwall, hornblende slate in Glen Tilt, gneiss in Cumberland and at Strontian, we shall have said enough in the present advanced state of Geology to secure the admission that granite was generated by heat.

The alternations which in several Countries obtain between granite and some of the older stratified rocks, as mica, schist, gneiss, &c., seem not at all irreconcilable with this view; but they will hereafter, when rightly understood, be found of great value in determining some peculiar conditions of the granitic eruptions.

Peculiar character of granite.

If we seek to understand the circumstances which have impressed upon granite characters so generally distinct from those of the other plutonic rocks, we shall find the following facts important. 1. Granitic rocks usually occur in very large masses below the whole, or a very large part of the whole series of strata, and were evidently formed under the pressure of a great body of water, if not under a pile of superincumbent strata. 2. They are so extensively spread beneath the neptunian rocks as to deserve, perhaps more than any other, the title of an universal formation. 3. Granite veins, in proportion to their minuteness and distance from the parent mass, grow continually finer in the grain and more porphyroidal in every respect. This effect is most completely seen along the sides of the veins. 4. In Countries where the great masses of igneous rocks are granitic, as for example Cumberland, the dykes and smaller masses are mostly of porphyry, or of a felspathic quartzose rock, of rather dubious character, which may be called syenite, porphyry, or unmicaceous granite, according to the locality. Such rocks occur about Wastdale head, in St. John's Vale, under Helvellyn, and in High Pike.

On comparing these general facts with Mr. G. Watt's experiments on the aggregation of fused basalt, there appears sufficient ground for believing that the very high crystalline character of granite is owing to its being produced at great depths where it was very slowly cooled to the point of crystallization. We may further venture the hypothesis, that porphyry is merely another state of consolidation of a similar felspathic compound, as trachyte has been supposed to be derived from older porphyries, or even from granite.

Comparison of ancient and modern pyrogenous rocks.

It appears, therefore, that among the older pyrogenous rocks we may distinguish the same two leading groups as among the modern volcanic products, characterised by the prevalence of some kind of felspar in the first, and of augite, hornblende, hypersthene, diallage, or some other analogous generally ferruginous mineral in the second; that in each of these occurs a great variety in the size, distinctness, and aggregation of the crystals, corresponding to the circumstances of the consolidation and differences of composition of the mass. The following short synopsis will express some of these relations among the older rocks.

Plutonic rocks are—1. Felspathic, as granite, porphyritic granite porphyry, amygdaloidal porphyry, claystone, pitchstone.
2. Hornblende, hypersthene, &c { Felspathic, as syenite, hypersthene rock, gabbro, serpentine.
3. Hornblendic, hypersthenic, &c. { As greenstone, basalt, trap porphyry, melaphyre, amygdaloidal traps, wacke.

On reviewing this series, and considering the manner of occurrence of the several members of it, we shall find that the prismatic structure is perhaps more generally developed in the augitic and hornblendic pyrogenous rocks, than in the felspathic branch, and that in both groups the highly crystallized varieties, as granite, syenite, and greenstone, exhibit less of this character than is common to granular claystone and glassy pitchstone, or fine grained basalt and trap porphyry.

Granite veins.

Another thing worthy of notice, is the circumstance that veins proceeding from the mass of a pyrogenous rock into the small cracks and short fissures of a stratified rock are almost peculiar to granite. This phenomenon is hardly ever noticed along the sides of a *dyke* or interposed bed of basalt or porphyry, and is at least very uncommon in connection with even large masses of greenstone. On the contrary, granite is very seldom found in dykes like the augitic and hornblendic rocks, though there is reason to believe that it assumes the form of overlying masses, and alternates in seeming beds with gneiss or mica slate. (S. E. of Ireland, p. 563.)

The variety of interesting considerations connected with granite will justify us in taking a more extended review of its mineral and chemical composition than were necessary while treating of other pyrogenous rocks. Granitic rocks have long been regarded as the source of most of the ingredients of sedimentary strata; a newer theory supposes that granitic rocks are continually forming beneath our feet, in quantities proportioned to the time, by the action of subterranean heat upon the hydrogenous strata. On both of these points some further information concerning the composition of granite will be useful.

Felspar.

Granite is essentially a felspathic rock. Whatever variations happen in respect of the quantity of other ingredients, felspar, in a crystallized state, is universally the basis of granite. In graphic granite the planes of crystallization of the felspar are continuous for great spaces; in porphyritic granite it generally happens that the axes of the prismatic crystals of felspar lie nearly in the same direction; but in common granites it is probable that the crystals of felspar lie in all directions, like the calcareous crystals of primary limestone. The felspar is red, white, green, &c.

Quartz.

Quartz, in a grey, transparent state, more or less evidently crystallized, is almost never absent from granite, but its quantity is very unequal. In graphic granite, quartz, in a sort of interrupted crystallization, is engaged among the laminæ of felspar, so as to assume angular and intersecting figures not unlike the characters of some Oriental language. In the porphyritic granite of Westmoreland the natural faces of the large crystals of felspar are impressed with very small bipyramidal crystals of quartz; and in other granites the quartz may generally, with care, be found crystallized in this form, so as to present on a polished face a regular or elongated hexagonal section. There seems also in some granites a portion of uncrystallized quartz, which is entangled among the other ingredients in irregular shapes. Binary granite, of quartz and felspar only, is seldom met with in Great Britain. It forms part of Muncaster fell in Cumberland.

Mica.

Mica, the third ordinary ingredient in granite, is occasionally very abundant in it; but sometimes absent. It is universally crystallized, generally in regular hexahedral plain laminæ, which enter or cut into the crystals of felspar and quartz, without being themselves interfered with. The direction of the crystals of mica is indeterminate; they do not occur in continuous laminæ, so as to cause the rock to cleave; for though porphyritic granite is in a certain sense cleavable, this arises from the parallelism of the crystalline axes of the felspar. Yet in some Cornish granites we occasionally see the mica aggregated together in a sort of shell, which gives a notion of some kind of lamination, arising perhaps from a limited intestine movement of the mass.

Order of crystallization.

It is generally presumed that the three most common ingredients of granite were crystallized together; by which is meant, that the consolidation of all the crystals was contemporaneous, neither preceding nor following another. This seems not always *exactly* true. In many cases we cannot doubt that mica was crystallized before the other ingredients. If we follow the indications of the penetration of crystalline forms, we shall find in several instances that the figure of the quartz was complete before the felspar was wholly consolidated; and perhaps, adding to this the consideration that the felspar in the solid parts of granite has, in general, only one, and that the primary form of its crystals, while quartz and mica invariably appear in secondary forms, we may venture to conclude that the felspar was the last crystallized, and, by consequence, has imparted to the mass its most important features. In many large grained granites are cavities, in which free crystallizations of the ingredients occur. In these cases the minerals show themselves in much greater variety of forms, especially the quartz and the felspar. The former assumes variously terminated prismatic forms; the latter is in rhomboids variously modified. (Baveno; Arran.)

Contemporaneous veins.

The aspect of granite is very often diversified by the occurrence of what are called contemporaneous veins; a term which is meant to convey the assertion that the difference of character which it marks was coeval with the formation of the rock. In the large grained granite of Arran and Cornwall, the contemporaneous veins usually appear as long, narrow, ramifying portions of finer grain and a different proportion of ingredients; sometimes with more mica, sometimes with less. The boundaries of these "veins" are indistinct, and the two structures gradually pass into one another.

It will be readily conceived, that a stone composed of crystals so much independent of each other may, especially when the felspar is not very predominant, be very far from solid; it may be very full of minute fissures. These are often clearly enough perceived, sometimes partially filled with small grains of quartz, steatite, felspar, mica, &c. When the stone is by any means subjected to decomposition, the several crystallized ingredients easily separate along these opening cracks.

Imbedded minerals.

It is almost unnecessary to enumerate the various other minerals which are disseminated in granite, except for the purpose of showing how many minerals may be developed from the same fundamental fluid mass. As all of them are *definite* compounds of certain ingredients, and only one simple earthy substance (quartz) remains as a residuum, it is no wonder they are mostly silicates of earthy substances, and that their relative quantity is very unequal, depending upon the possible atomic combinations which should exactly exhaust all the ingredients except the superfluous quartz.

Silicates. Tourmaline, topaz, zircon, cordierite, epidote, garnet, lepidolite, petalite, triphane, steatite, talc, schorl, hypersthene, hornblende, augite.

Aluminates. Cymophane, beryl, pinite.

Sulphuret of bismuth, sulphuret of molybdenum, tungstate of iron, rutile, oxide of tin, graphite, oxide of iron, &c.

Restricting ourselves to the more common varieties of granite, we may observe, that the difference in the crystallization of the ingredients could not be determined *à priori*, from considerations of the relative fusibility of the minerals; because, in fact, these minerals were all developed from one uniform melted mass, in which the only distinct parts were the elementary substances of silica, alumina, lime, potash, oxide of iron, &c.; and it would depend chiefly upon the relative cohesive forces and chemical attractions of certain proportions of these ingredients what crystals should be first generated. In trinary granite, for example, it may not be that mica and quartz were crystallized before felspar because this latter is the more fusible substance, but because out of the mingled mass of elementary substances the particular combination which constitutes mica was endowed with the highest attractive energy. Mica might be formed out of a melted mass at a temperature very far below that required for its own fusion; this being separated, there would remain a silicated felspar, from which the excess of silica being separated, it might depend upon the state of the mass as to heat, whether both quartz and felspar should crystallize together with mutual penetration, or the former impress the latter.

Elementary composition of granite.

If we assume granite to consist of 20 parts of felspar, 5 parts of quartz, 2 of mica, the fused glass from which, on cooling, these minerals were crystallized, must have contained about

Silica ...	1853	of which	1353	formed felspar and mica, leaving a residuum of silica.
Alumina .	404		104	
Potash ...	282		282	
Lime	10		10	
Ox. iron ..	44		44	
Ox. mang.	3		3	

Had the proportions of alumina and the metallic oxides been greater, it is probable that more mica would have been formed; had they been less, less mica and more felspar might have resulted; and the proportions of the ingredients might have been such that the mica and felspar might be provided with their constituent potash and other parts, hornblende or augite, or hypersthene, with their lime, magnesia, &c., and a residue of quartz remain.

According to the rate of cooling we might have a large grained or fine grained granite, or a nearly compact rock: if the quantity of felspar was very great, and the cooling rightly proportioned, the mica and quartz might be crystallized in a compact, earthy, or glassy uncrystallized basis. Thus felspar porphyry would be produced from the same ingredients as ordinary granite; and the whole investigation appears to teach us that the mineral characters of pyrogenous rocks depend as much upon the circumstances of their solidification as upon original differences of chemical composition. With this all observations on these rocks fully agree; and it is, therefore, in a right spirit of philosophical generalization that Geologists have now accustomed themselves to view the whole series of plutonic and volcanic products as the varied results of one original mode of calorific action operating under a variety of conditions as to cooling, pressure, limitation of space, and other influential circumstances.

SECTION 3.

Relative Age and characteristic Phenomena of Pyrogenous Rocks.

Age of plutonic rocks.

Were our inquiries concerning the relative age of plutonic rocks to be answered only by appeal to observation of the phenomena which they present in contact with one another, the research must be abandoned. For they neither show themselves so often in connection, nor display, when in connection, such marks of relative antiquity as to permit us to recognise more than one general truth, *viz.* that granite is very often the oldest and basalt very often the youngest of these rocks. But by studying separately the age of each of these rocks in relation to the strata which adjoin it, we obtain a more extensive and more exact series of determinations concerning the periods when they have been erupted through the consolidated crust of the earth. The importance of these determinations in inductive Geology is so great as to demand a preliminary statement of the mode of reasoning employed in obtaining them.

1. When in any Country a certain class of rocks, as for instance the slate rocks, have been convulsed and thrown

Age of plutonic rocks

into new positions before the deposition of another set upon them, as for instance the carboniferous rocks, and we find occupying the axis or nucleus of the dislocation a mass of granite, it is certain that such granite is older than the carboniferous system because it was uplifted with the older slates. If, in addition, this granite sends veins through the slate rocks so as to prove that it was uplifted in a melted state, we must infer that it is of more recent origin than those slates; and, in fact, that its antiquity is exactly measured by the date of the convulsion.

If there be no veins thrown off from the mass of granite, and no other satisfactory proof of its having been uplifted in a melted state, the age of the igneous rock is indefinable, except by saying that it is older than a given stratified rock. Such a case occurs in the Ord of Caithness. It appears, then, that in any case of convulsion the era of the elevation of the igneous rock is determined by the convulsion, but whether it was actually generated at that time from a melted state, requires other evidence. Now this consolidation from a melted state is what fixes the age of an igneous rock. Granite may, perhaps, have remained melted in the deep parts of the earth through many geological periods, but its age as a rock is counted from the period when its fusion closed.

2. In Derbyshire the carboniferous limestone is interlaminated for great lengths by an igneous rock, (toadstone,) which has evidently been poured out at certain intervals by an ancient submarine volcano while the limestone was in formation. The age of such a rock is fixed by the age of the limestone.

3. The basalt of dykes which pass through certain strata, is, of course, not more ancient than the newest strata divided; if at any point the dyke should be covered by newer strata which are undisturbed by the dislocation accompanying it, we may generally admit that the basalt is older than these strata. Such a case, perhaps, occurs in the dykes of the Durham coal field, which do not penetrate the magnesian limestone.

These instances are sufficient to show the truth of two propositions of general application to this subject.

When igneous rocks accompany convulsions, we can always fix the minimum of their geological antiquity; when they throw off veins or intrude in the shape of dykes, or interpolated beds, among stratified rocks, we are able to assign the maximum of their antiquity.

Guided by these views, and restricting our illustrations as much as possible to the British Isles, we may proceed to describe some of the characteristic phenomena occasioned by the appearance of plutonic rocks, and to fix the eras of their production.

First, we shall describe the general features of a district remarkable for the number of these rocks brought into a small compass and presenting diversified effects, and then select instances proper to make known the characters of each.

We shall take an example of the phenomena of pyrogenous rocks in general from that gem of Huttonian Geology the justly celebrated Island of Arran, an examination of which may be safely pronounced almost indispensable to a complete geological education.

Arran.

General features.

The Island of Arran has been very often described, and by eminent Geologists. Jameson, Macculloch, Necker, Murchison and Sedgewick, Oeynhausen and Von Dechen, have all written ably on the inexhaustible subject of this little world of geological phenomena; and were it not for a reluctance to add to this weighty literature, other voyagers would be unable to restrain themselves from describing some neglected but curious phenomena. The leading features of Arran are its mountainous and truly Alpine scenery in the Northern extremity, and the elevated plateaux of its Southern portion. These latter are generally composed of trap rocks, partly syenite, partly porphyry, partly greenstone, with many dykes of greenstone and pitchstone passing through the red sandstone strata which appear around the coasts. The highest Northern eminences are granitic mountains forming the nucleus of a great conical elevation of slate rocks, which, overlaid by the red sandstone formation, (see p. 609.) form a narrow but unequal zone round the granite. The small size of the Island combined with the elevation of the mountains (nearly 3000 feet) gives to the short glens a very sudden depth, and permits the cliffs to show the great curvatures of strata. Dykes and overlying masses of greenstone, felspathic and trap porphyry, various sorts of claystone and pitch-stone, are seen abundantly both on the Eastern, Western, and Southern coasts; and so perfectly are all the phenomena exhibited, that it is difficult to imagine any space of the same limited extent more worthy of being studied for the purpose of understanding the mutual relations of pyrogenous rocks.

That the granite of this Island was upheaved in a melted state seems sufficiently demonstrated by the fact of its throwing veins through the surrounding slate rocks: this phenomenon may be very well studied at Tornidneon. That its elevation was subsequent to the deposition of the whole red sandstone system seems also proved by the curvatures which these strata have undergone. This would give for the elevation of the granite of Arran a period considerably later than that usually assigned to the principal part of the Highland mountains, and, perhaps, agreeing with the rising of the syenites of Malvern and Charnwood forest.

The granite is, as far as can be known, the oldest pyrogenous rock to be seen in the Island, for it is traversed by dykes of basalt and pitchstone, like those which cross the red sandstones. It is observable, however, that these dykes are most numerous at some distance from the granitic centre. At Corygills, at Lamlash, and Tormore, they are exceedingly abundant in the red sandstone, while in the North-Eastern face of the Island, where that rock is nearer to the granite, fewer dykes appear, and about Loch Ranza the slate is still less divided by them. Perhaps we may venture to add another generalization; *viz.* that these dykes are most abundant beyond the line of violent flexure of the strata from their horizontal position. After measuring with care the directions and breadths, and noting the characters of forty-four dykes, chiefly of greenstone, between Brodick and Lamlash, and also those at Tormore, it did not appear to the writer of this notice that any other dependence of the direction of those dykes upon the local centre of the granitic eruption could be traced.

While in the Eastern side of the Island, about Corygills, the dykes in the red sandstone are chiefly greenstone and basalt, with a sparing admixture of felspathic and porphyritic claystone and pitchstone, those of Tormore, in light coloured sandstone, are chiefly pitchstone, claystone, and trap porphyry. On both sides occur interposed beds of pitchstone, divided into columns; on the East are overlying greenstones in rude colonnades; on the West trap porphyry columns; on the East the claystone dykes are highly prismatic; on the West occur many interposed beds, and an arched vein of claystone. The pitchstone of the Eastern side is black or green, that of the Western coast often variously coloured and graduating to something like hornstone, or to claystone. It is, in one point, at Tormore, of that concretionary structure which reminds us of some kinds of obsidian and sphærulitic traps.

Alterations of stratified rocks.

The effects of the pyrogenous rocks upon those in contact with them are less striking in Arran than in many other situations. No new minerals are produced in the slate where the granite touches it, nor in the red sandstones where they are bordered by the greenstone dykes. This hardening is very various in degree, and the causes of these differences are not very evident even upon the examination of many cases. The hardening effect is sometimes communicated to the distance of two or three feet into the neighbouring rock, but generally not to more than a few inches. The hardened parts sometimes stand up in narrow crests. Where dykes cross, it has been found that one of the planes of intersection of the greenstone dykes has been marked by the occurrence of a very narrow band of black pitchstone. The base of the pitchstone pillars of the interposed bed in Corygills is softened, where it touches the sandstone below, to a kind of kaolin.

It is impossible to say what was the geological epoch of the pyrogenous eruptions of Arran, further than that they were posterior to the whole red sandstone system there. If this be correctly taken by Murchison and Sedgwick to represent both the old and new red sandstone systems, they are later than most of those known in England, and, for aught we can tell, they may be as modern as the basaltic eruptions of the North of Ireland.

Geographical relation of pyrogenous rocks.

It is remarkable that, amidst all the profusion of greenstones, pitchstone, claystone, and porphyritic dykes, which appear a little remote from the granite, no granite dyke is seen; while in the granite, whose elevation seems to be the local centre of all those exhibitions, no hornblende or augite occurs. That granite and the trap dykes are of different antiquity has been shown before; but it seems also to be implied either, first, that at successive epochs different rocks lay melted under the same localities; second, that the local production of pyrogenous rocks is somehow governed by relations of level or distance, or subject to an obscure reciprocity of position. It seems worth while to follow out this idea. Along the Penine chain, the axis of dislocation shows, at points, granitic and greenstone rocks, but very few mineral veins are wrought. The slopes a little removed from this mountain edge contain many valuable lead mines. The mining district of Shropshire, described by Mr. Murchison, appears related to the greenstone ridge of Corndon nearly in the same way; for though along this axis no mines occur, they abound in a line at a small distance parallel to it. Perhaps to these analogies we may add the instance of the diversified porphyritic masses which run irregularly parallel to, but removed from the granitic axis of Cumbria. Finally, to rise to a greater generalization, Von Buch's views of the relations of the granitic axis of the Alps and the augitic porphyries (melaphyre) along their Southern flanks appear to be decidedly analogous, and there seems at least thus much to be inferred from the points of agreement among these several examples of the relative position of ignigenous rocks, that the elevation of an axis or nucleus of granitic rocks was attended by very numerous fissures at a small distance removed, which, after some geological interval, were filled by rocks of a quite different nature from those which were erupted at the time of the first disturbance.

Granite.

Antiquity of granite.

It might be doubtful whether any granite visible in the British Islands could claim greater antiquity than the upper or graywacke slate rocks, except for the cases of alternating granite and mica slate, quoted from Mr. Weaver, p. 563. The granite of the Cornish chain in some places throws veins into the adjacent clay slates, and generally appears to change very greatly the nature of those rocks, so that we are compelled to rank it as a more modern product. The granites of Cumberland and Westmoreland, and those of the Grampians, if their age be judged of from that of the convulsions accompanying them, and from the veins which they throw off, must be pronounced to be of nearly the same antiquity. In the Island of Arran, the granite seems to be not so old as the red sandstone which overlies the carboniferous limestone; in the Alps it must perhaps be supposed to have been in fusion ever since the tertiary epoch.

Granite veins.

A few years ago granite veins were considered as rare eruptions, but at present it is difficult to find a satisfactory example of any extensive tract of granite, without the occurrence of such ramifications through the neighbouring rocks. They occur in Cornwall, Cumberland, and Arran, in Ben Cruachan, at Strontian, in Glen Tilt, and generally throughout the Highlands. The same is true for the Continent of Europe; and perhaps we may no where find a better example of the elevation of granite in *a solid form*, than that described by Murchison at the Ord of Caithness. This granite, on its Northern flank, supports the old red conglomerate, whilst to the South it occupies a cliff on and near the shore, the verge of which affords a remarkable breccia, compounded from all the beds of the oolitic series that occur on this coast. This breccia of sandstone, shale, and limestone, is tilted off from the granite wherever that rock protrudes upon the shore, whilst the strata are regularly developed where the granite recedes into the interior. No veins or portions of the granite are to be met with in or above the oolitic breccia, which, by its disturbed position, appears to fix the maximum of antiquity of the elevation of the granite not beyond the age of the coralline oolite.

Tornidneon.

The granite veins of Tornidneon in Arran pass from a body of very coarse grained granite through nearly vertical laminæ of dark quartzose clay slate; the line of junction dividing the whole side of a hill. One of the veins encloses fragments of slate, divides itself into branches, which cross the laminæ of slate, cutting off both the quartzose and argillaceous laminæ. The granite becomes much finer grained along the veins, and nearly in proportion to their smallness; so that in the narrowest veins it is nearly compact. Strings of fine grained granite divide the coarser sort. (See pl. vii. fig. 1.) (1826.)

Glen Tilt.

In Glen Tilt, Dr. Macculloch has described numerous and valuable facts of this nature. At the bridge beyond Forest Lodge, granite, hornblende slate, and primary limestone are very curiously associated. Veins of red granite here divide the other rocks, and inclose fragments of them. The singular interlacements of the rocks here will be best understood by the sketch, pl. vii. fig. 2, taken on the spot in 1826.

1. Primary limestone laminated by hornblende and red felspar in curved lines or detached masses, round which the laminæ of limestone bend, crossed by granite and red felspar veins.

2. White quartz rock and red felspar crystallized.

3. Felspathic rock, red, with layers of black hornblende.

4. Limestone laminated with felspar.

5. The same with less felspar.

6. Hornblende and felspar in layers.

7. Laminated limestone.

(*a.*) Red felspar vein—a little quartz.

8, 9. Hornblende, with layers, masses, and veins of white quartz, and red felspar, which substances often occur together, making binary granite of very large grain.

10. Limestone, with red granite veins.

11. Limestone, red granite veins, and white *calcareous spar veins, which divide the granite veins.*

12. Red granite, composed of red compact or crystallized felspar, white quartz, and black or grey mica, and incloses hornblende masses which are divided by veins of granite ramifying from the general masses of that rock.

Cornwall. The extremity of Cornwall has long been famous for the great variety of curious phenomena connected with the granite veins which there divide the argillaceous slate, hornblende slate, and greenstone rocks, all included by the miners under the title of killas. So many writers of eminence, both English and foreign, have described and reasoned upon these occurrences, that it is difficult to select from the immense variety. The following is Mr. Majendie's account of the veins at Mousehole, three miles South-West of Penzance. (*Cornwall Geol. Soc. Trans.* vol. i.) "At this period the clay slate ceases, and the granite commences, forming a promontory which runs out in a Southern direction from the central ridge. The slate is of a grey colour; it is in strata nearly horizontal, but having a slight dip to the East; it increases in hardness near the junction. The granite, which is generally coarse and porphyritic from the large imbedded crystals of felspar, becomes here of a finer grain, with black mica and light flesh-red felspar. On the North it laps over the schistus. At this spot numerous granite veins, varying in width from about a foot to less than an inch, pass through the slate; the two principal veins proceed nearly East from the hill above, for more than fifty yards, until they are lost in the sea. One of these, not far from its first appearance, is divided and heaved several feet by a cross vein consisting of quartz intermingled with slate; fragments of slate appear also in the granite veins. The most remarkable vein, after proceeding vertically for some distance, suddenly forms an angle, and continues in a direction nearly horizontal, having slate above and below."

The killas at this place has much the aspect of greenstone, and it appears generally true that the clay slate is much altered in character round all the granites of Cornwall and Devon. (See Mr. De la Beche's *Geological Map, Devon.*) The veins of granite are generally most fine grained towards the walls. Von Oeynhausen and Von Dechen mention three principal veins at Mousehole, one 3½ to 10 feet wide; quartz veins cross the direction of the granite veins, and sometimes divide them and apparently alter their character. Schorl occurs irregularly in the granite, and in some of the quartz veins. In other localities, veins of this mineral present interesting phenomena. The intricate character of the venigenous masses of Mousehole will be best understood by consulting the diagram, pl. vii. fig. 3, copied from the sketch of the distinguished Prussian Geologists above named.

At Cape Cornwall, a granite vein *heaves* a quartz vein in a direction contrary to the general law, stated in page 541. In the Lizard district granite veins divide serpentine.

Felspar Porphyry.

Ben Nevis. The abundance and variety of felspar porphyry, in great masses on the summit of Ben Nevis, and in the awful valley of Glen Coe, is familiar to every traveller in the Highlands; the porphyry of Ben Nevis has been shown by Von Oeynhausen and Von Dechen to have been erupted through the granitic basis of that mountain; the diversified porphyries along the vertical precipices of Glen Coe send veins through the subjacent granites, in number proportioned to the proximity of the situation to the great mass of porphyry This rock is not columnar; (Macculloch;) it varies through every stage, from claystone to felspar porphyry, the different varieties being sometimes gradually and sometimes suddenly connected. Breccia, composed of fragmented claystones and porphyries, (like those on Ben Nevis, and some in Cumberland,) are often seen in Glen Coe.

In the mountain of Cruachan, which overlooks Loch Awe, the hornblendic granite and schist rocks are traversed by a great variety of large felspar and trap porphyry dykes, and some changes of appearance happen to the clay and mica slate, very difficult to be described. Macculloch (*Geol. Trans.* iv.) describes the porphyry dykes as perpendicular, varying from 3 to 50 feet in breadth, traversing alike the schist and the granite veins which divide it, but not in any degree intermingling with either. Dykes of porphyry, of different kinds and colours, may run near or in contact with each other, but in all cases these and other dykes of basalt or trap porphyry are very distinct at the edges, though firmly united to the rock which encloses them. Pl. vii. fig. 4, shows veins of granite traversing the schist of Cruachan, themselves crossed by dykes of two kinds of porphyry. (*Geol. Trans.* iv. pl. vi.)

Cumbrian mountains. In the Cumbrian mountains felspar porphyries occur in many situations, and with a great diversity of character; some have a basis of translucent grey or green felspar, and included crystals of glassy felspar and quartz; others are composed of a red, opaque, granular felspar basis, and red felspar and quartz crystals; the basis of others is compact felspar or hornstone, and some have a dark but not basaltic base, with small white opaque felspar crystals. Most of them, like the amygdaloids and greenstones of the same region, occur in overlying masses as well as dykes, but real alternations of them with the slates can hardly be substantiated. They seem to have a Geographical dependence on the foci of granitic eruption, of a peculiar kind. They are not abundant in or *very* near to the granite of Wastdale, Skiddaw, or Shap, but they occur at small distances from each of those masses. The Valley of St. John's shows pale red felspar porphyry overlying slate, well crystallized red porphyry in Armboth fell, and various kinds of felspathic rocks under Helvellyn. Dykes of variable greenish porphyry divide the slates of High Pike, and a solitary red dyke ranges East and West of the granite of Shap fells. No porphyry occurs very far from the granites.

In North Wales felspathic porphyries appear so connected by alternate bedding with the slates, as to have been subjected to the same elevations and undulations of dip; and thus not only prove their high antiquity, but also suggest views as to the frequent recurrence of igneous action at the same points of the ancient bed of the sea during the period of the primary slates.

Cornwall.

Consistently with our views of the origin of the crystallized rocks, we may perhaps be right in believing that all the complicated, wholly or partially, crystallized rocks, composed of felspar, quartz, and mica, which are included between and which traverse the real slaty rocks of Cornwall, are either the result of submarine eruptions during the formation of the slate; of the subsequent action of the heated granitic masses upon the killas; of posterior eruptions of melted rock into fissures caused by convulsion, or of some gradual conversion and transfer of mineral ingredients, such as we know to have occurred

It is hazardous to reason on phenomena so remarkable as those of Cornwall, without reference to other districts; nothing but prejudice or indolence will permit Geologists, acquainted with other districts, to neglect the singular and curious facts connected with the Devonshire and Cornish chain. We may freely admit that they, in some cases, point to agencies not yet familiar to our philosophy; that a full examination of the whole series of granites, porphyries, serpentines, and killas, and of the disseminated and venigenous minerals in them, will kindle a brilliant light in the most secret laboratory of Nature; but one thing is wanting, an exact description of *all the characteristic facts observable in each particular case*, without the adornment of theory, or the disarray of new nomenclature. (See Conybeare, Buckland, and Sedgwick, *Geol. Trans.*; the *Trans. of Cornish Geol. Soc.*; and Dr. Boase's recent volume.)

Syenite.

Malvern.

The syenite of Malvern is not older than the old red sandstone, which it throws off from its slopes and penetrates by a lateral extension or dyke, nor so young as the new red sandstone which lies level at its feet; the same limits of age must be assigned to the similar rocks of Charnwood forest, which appear under very analogous circumstances. The partially syenitic rocks of Carrock fell in Cumberland, may, very probably, be older. We shall not assign this name to the variable rock of Red Pike and Scale Force: according to Weiss, the syenite of Weinbola near Meissen is superimposed on the green sand system. The Malvern hills, long since described with much ability by Mr. Horner, and a dyke apparently dependent on them lately investigated by Mr. Murchison, will serve to illustrate the phenomena attending syenitic extrusions.

The picturesque chain of the Malverns rises at its centre to 1444 feet above the sea, and looks down over a vast and beautiful region. On the Eastern side the descent is abrupt to plains of horizontal new red sandstone, on the Western more gradual and diversified by ranges of woody hills whose bearing is parallel to that of the chain. Beyond are the slate mountains of Wales. Many small narrow valleys run to the East across the line of the chain.

The verdant surface of these hills, and the circumstance that the pyrogenous rocks are very much decomposed and fissured near the surface, prevents very frequent observation. The great mass of the rocks is of a syenitic rather than granitic character, varying, however, much as to the relative proportions of hornblende, mica, and quartz: the felspar is usually red, epidote, magnetic iron, pyrites, and other minerals occur, and the aspect of the rock is sometimes that of greenstone. Veins of granite traverse the neighbouring rocks. Veins of sulphate of barytes, calcareous spar, and epidote, red hematite, &c., occur in the syenitic rocks.

Elevation of strata.

The stratified rocks which are dislocated along the line of the Malverns are best seen on the Western slopes, the oldest of them belongs to the fourth group[*] of the greywacke series of the Welsh border. (See p. 567.) The sandstones of this and the limestones and shales of the superior groups are partly vertical, or partly *overthrown* to the West, so that for some distance to the West the series of strata *appears inverted*, and the really newer rocks come out from under the older. (*Geol. Trans.* vol. i.) Much local confusion and disturbance of declinations accompany these general indications of violent upward heaving along the axis of the chain. Mr. Horner's very judicious reflections on the bearing of the phenomena of the Malvern upon the then prevalent discussion of the Wernerian and Huttonian Theories of Geology, will be perused with great satisfaction and pleasure as anticipating many of the clearest arguments known in the present advanced state of the Science. As the unstratified rocks have been thrown up along a line from North to South, the bearing of the elevated strata ought, in general, to be parallel to that line, and this has been shown to be the case: the force would be greatest at the point where the unstratified rocks burst forth, and accordingly we find the strata there generally vertical, or even thrown back and in some degree inverted.

The same phenomena of inverted strata are observed by Mr. Murchison parallel to the Abberley hills, which are on the prolongation of the Malverns; and we are indebted to him for an interesting notice of a dyke of dark green syenitic rock, at Brockhill near the Teme, composed of hornblende, felspar, and quartz, eight paces wide, directed West 5° North, and East 5° South. The syenitic rock is prismatic at the sides, the prism lying across the dyke, whose walls are formed of old red sandstone, here of a green tinge, and marls. In contact with the dyke and for 20 feet distance the sandstone is hardened, is of a deep purple colour, and has lost its mica; the marls are altered by the diffusion of carbonate of lime through their mass. This dyke is considered as a lateral effect from the great North and South axis of igneous rocks of the Malvern and Abberley hills.

Hypersthene Rock or Hypersthenic Syenite.

Hypersthene rock forms the pinnacled mountains of Cuchullin, part of Carrock fell in Cumberland, certain dykes in Radnorshire, and is not unknown in Cornwall;

---

[*] In the *Phil Mag.* for June 1834, Mr. Murchison has published a new arrangement of these groups, in which the second and third groups are united.

it also occurs in Yorkshire in veins passing through the basalt of the carboniferous limestone series. The exhibition of hypersthene rocks in the Valteline has been described by M. Necker.

This rock may be very generally described as a syenite, of which the felspar is pale flesh-colour, white, or greenish, and the hornblende is replaced by hypersthene, either in very distinct, large crystals, or small concretionary masses. In the latter case it can hardly be distinguished from common greenstone. In Cornwall, Radnor, and Cumberland this rock may be admitted to be of later date than the greater part of the slate system; in Yorkshire it is contemporaneous with the great basaltic formation of the carboniferous epoch; in the Isle of Skye it is probably more recent than the oolitic era; in the Alps it forms a part of the mineralogical axis, and may have been thrown up even since almost the whole tertiary strata of the basins of Europe.

The Valteline.

M. Necker, in his account of the Valteline, establishes the fact, that the granitic eminences which rise along the axis of that singular *valley of elevation*, pass by degrees to common syenite, and afterwards to syenite with hypersthene, in large, small, or even minute crystals, of black or green colour, and metallic reflections. The felspar has a violet tinge. The greater and hypersthenic axis of the valley is coincident with the central line of the great chain of the Alps, from South-West to North-East, and the stratified rocks are vertical on each side, for some distance; afterwards they take opposite dips to the North-West and South-East. The order of succession may be stated to be gneiss, mica schist, changing to talcose and chloritic schist and clay slate. Veins of fine grained granite pass through the hypersthenic rocks and through the mica schist, sometimes holding fragments of this latter, and quartz veins with black tourmalines divide the granite.

Skye.

The Cuchullin mountains in Skye, rendered classical by Macculloch's descriptions, surround the desolate lake of Coruisk, a grand amphitheatre of steep and barren rocks, which decompose so little as to yield neither sand nor gravel to the torrents. A great variety of appearances is presented by the mixture of the felspar and hypersthene in these rocks, as to crystallization and colour. In some localities the mass is fine grained, and in others graduates to common syenite or greenstone. Von Oeynhausen and Von Dechen state that the hypersthene rocks pass into compact greenstone; and that the common syenite lies on the hypersthene rock, with an abrupt and distinct junction. One of the most interesting facts connected with this group of rocks is the transmutation of the lias into white granular and compact limestone, where it is in contact with the syenite and trap rocks. This effect happens more constantly at the junction of the lias with syenite than with greenstone or trap; in the latter case it sometimes happens, sometimes not. The hypersthene rock seldom adjoins the lias; where it does, like greenstone or trap, it both intersects and covers it.

Gabbro, Granitone, Euphotide, Diallage Rock, Serpentine.

It is to M. Von Buch that we are indebted for pointing out the importance of the rock, composed of saussurite, or felspar and diallage, called gabbro, or granitone, in Northern Italy. The abundance of serpentine in the Pyrenees, Apennines, and other parts of the South of Europe, has long been remarked. Diallage rocks are equally abundant, often occur in connection with the serpentine, and there is now no doubt as to the fact that these two rocks are very intimately related. Few conclusions of this nature appear better authenticated by observation than the gradation of diallage rock into serpentine, in the Alps, the Apennines, Corsica, and Cornwall. Gabbro has been employed in architecture by the Romans, and by the family of Medicis at Florence. The town of Vienna is said to be paved with it.

Stratification of serpentine.

Generally, observers agree in representing both gabbro and serpentine as unstratified rocks. When portions of them are included between strata of gneiss, mica, schist, &c., they may be viewed as interposed masses. But Macculloch positively affirms that in Unst the stratification, both of diallage rock and of serpentine, is certainly evident; and he compares the cases where no stratification can be traced in the latter to analogous instances in primary limestone. The latter, however, is by far the most abundant case; and perhaps, taking into account the circumstance that in Unst the rocks alternate and graduate into micaceous, chloritic, and argillaceous schists, we may reasonably inquire whether the stratified varieties of diallage and serpentine are not recomposed rocks altered, like some gneiss, by subsequent application of heat.

In the Northern Apennines, Brongniart has remarked the following general order of succession downwards. 1. Serpentine. 2. Diallage rock, in the upper part assuming the aspect of serpentine, (at Rochetta, North of Borghetto, near Spezia,) consisting partly of red crystallized limestone. 3. Jasper rock in thin laminæ. Below these are limestones and marly schists, common in the Apennines. In Monte Ramezzo, North-West of Genoa, the serpentine is placed on limestone and talc schist, the limestone is in thin tortuous beds, and is as it were dissolved with the shining slate and steaschist. The direction of the serpentinous masses in the Northern Apennines, to which the elevation of that part of the range is ascribed, is East South-East, which is the same as that of the Pyrenees, and of some serpentine rocks about Como.

Greenstone.

Scotland has been long and not unjustly considered classic ground for the pyrogenous rocks. We shall take as an example of the occurrence of greenstone, the phenomena in the vicinity of Edinburgh, which have contributed so powerfully to support the philosophical fame of Dr. Hutton. The interesting eminences of Arthur's Seat, Salisbury Craig, the Calton Hill, and Edinburgh Castle, are all composed of trap rocks associated with various sandstones and shales of the carboniferous system, and the labours of Art have added to the admirable exhibitions of Nature.

Salisbury Craig.

In Salisbury Craig is a very fine section of unstratified greenstone enclosed between stratified sandstone, conglomerate, shale, and ironstone nodules, and it is easily seen that both the igneous and sedimentary rocks are altered at their formation. Masses of sandstone and conglomerate, of various forms and magnitudes, are insulated in a confused manner within the greenstone, and portions of greenstone interposed among the sandstones. No dyke appears, but small veins of calcareous spar, occasionally metalliferous, cross the line of junction. The accompanying drawings and references will sufficiently explain the most interesting phenomena observed.

Pl. vii. fig. 5, gives a general view of the face of the cliff, as it appeared to the writer in 1826. The letters of reference, *a*, *b*, *c*, mark points of which details are given below. On a nearer examination, the point *a* shows greenstone gradually changing to a red colour and finer grain near its upper surface, on which rest beds of sandstone, ironstone, and shale, as under.

1. The upper part of a greenstone mass, fine grained and of reddish colour. Veins of calcareous spar, with micaceous iron ore, divide the upper part of this mass, and pass through Nos. 2 and 3 above.

2, 3. Mass of petro-silicious sandstone, mixed with softer green portions.

4. The same sort of hardened sandstone, with less of the softer parts, (here and there a purple tinge.)

5. Argillaceous, compact, hard shale of a purplish or green colour, and subconchoidal fracture.

6. Red argillaceous ironstone in green shale.

7. Sandstone beds, reddish and indurated.

At the point *b* (fig. 6) a nearly similar series of alternating stone and shale rests on very similar trap. A portion of sandstone is engaged in the trap, and other signs of violent intrusion occur.

At the point *c* hard red sandstone flags, without ironstone, rest on reddened greenstone.

A large quarry at the South end of Salisbury Crag affords an excellent section of sandstone beds *below* the greenstone. Fig. 7 and 8 are taken from this quarry.

In fig. 7, the greenstone, reddening below, rests on jasperized sandstone, which is much broken and confused in places; below this is green shale, covering red and white sandstone with conglomerate. Fig. 8 shows portions of sandstone enclosed in the trap, which grows redder towards the contact with the strata below. The aspect of a portion of sandstone fairly enclosed in trap is seen in fig. 9.

Some late observations of Lord Greenock on the appearances presented by a section of the compact greenstone and sandstone strata in the Castle Hill, Edinburgh, show the effect of convulsions acting upon both of those rocks since the eruption of the lithoid lava. At some points of this hill the usual transformations of the sandstones, &c. happen in contact with trap, but in one place beds of sandstone and marl are seen in a state of great disturbance, thrown in angular positions upon tabular greenstone, and not in the slightest degree altered as to hardness or aggregation at the junction. Possibly, the explanation which applies here, *viz.* that the junction of the igneous and stratified rock has been occasioned by convulsive movements, which have lifted them both in a *solid* form, may be found applicable to some other cases in which trap rocks appear to exercise no transforming influence on the contiguous rocks.

Basalt.

The researches of Dr. Berger, Dr. Buckland, and Mr. Conybeare, on the North-East of Ireland, have furnished a highly interesting Memoir in the *Geol. Trans.* vol. iii. from the pen of the latter Geologist. The coast between Belfast Lough and Lough Foyle is one boundary of a large tract reaching Westward to Lough Neagh, and including the river Bann, which is almost wholly occupied on the surface by basaltic rocks rising at intervals to eminences of 1320, 1820, and 1864 feet above the sea. Under this immense overlying mass of basalt are found several members of the English series of strata not known elsewhere in Ireland. 1. Chalk, agreeing with the lower beds of the English series. 2. Mulattoe, an Irish name for the green sand of English Geologists. 3. Lias limestone, (without any other rock of the oolitic system.) 4. Beds of red marl and gypsum salt, resting on variegated sandstone. 5. At the North-Eastern and South-Eastern extremity, coal measures, consisting of red sandstones and shales with inferior coal, appear below all the other strata. The mulattoe and lias are often wanting in the section. The superincumbent basalt is estimated to have an average thickness of 545 feet, (in Benyavenagh it is 900 feet, in Knochlead 980 feet,) and its superficial extent 800 square miles.

The phenomena presented by the basalt, exposed along so great a length of coast, are various and remarkable, and we are not only delighted with the magnificent colonnades of Fairhead, and the geometrical pavement of the Causeway, but instructed by the clear exhibition of the effects of dykes dividing both the congenerous basalt above and the calcareous strata beneath.

The immense mass of trap rocks in this district exhibits, besides basalt, which is the most abundant material, greenstone, clinkstone porphyry, wacke, and red ochre. Near the Causeway, the cliffs, according to Dr. Richardson, consist of alternating basalt and red ochre, in the following order downwards.

1. Basalt rudely columnar, 60 feet.

2. Red ochre or bole, 9 feet.

3. Basalt irregularly prismatic, 60 feet.

4. Columnar basalt, 7 feet.

5. Intermediate between bole and basalt, 8 feet.

6. Coarsely columnar basalt, 10 feet.

7. Columnar basalt, the upper range of pillars at Bengore Head, 54 feet.

8. Irregularly prismatic basalt. In this bed the wacke and wood coal of Port Noffer are situated, 54 feet.

9. Columnar basalt, forming the Causeway by its intersection with the plane of the sea, 44 feet.

10. Bole or red ochre, 22 feet.

11, 12, 13. Tabular basalt, divided by thin seams of bole, 80 feet.

14, 15, 16. Tabular basalt, occasionally containing zeolite, 80 feet.

The stratified rocks in contact with the trap have undergone remarkable changes in several localities.

At Portrush, the trap (a rudely prismatic greenstone) overlies and perhaps alternates with a flinty slate, which contains numerous impressions of ammonites, belonging to the lias shales. This transformation of lias shale, which reminds us of the more extensive phenomena of the same kind in Savoy, was formerly adduced as an argument for the aqueous origin of basalt! Most of the alterations of stratified rocks on this coast are effected by basaltic dykes, which divide both the overlying masses of trap and the subjacent strata.

At the foot of the hill called Lurgethan, basaltic dykes traverse the red sandstone conglomerate, which is indurated near the contact so as to resemble compact hornstone.

The coal measures, underlying the basalt of Fairhead, are crossed by dykes which have changed the ordinary shale into flinty slate, hardened and pyritized the sandstone for 15 yards, and converted the coal to a cinder. The chalk is affected by many dykes to such a degree as to be converted to a real marble, for 10 feet or more from the side of the basalt.

The order of effects is first a yellowish tinge of colour, then a bluish-grey colour and compact texture, then a fine-grained arenaceous aspect, next a saccharine granulation, and finally close to the dyke the chalk is altered to a dark brown crystalline limestone, with flaky crystals as large as those in primary limestone. The flints in the altered chalk assume a grey-yellowish colour; the altered chalk is highly phosphorescent when heated. Examples occur near Belfast, at Glenarm, in Rathlin, and other places. Near the top of the stratum of chalk which crowns the cliffs of Murloch Bay, is an interposed bed of wacke 5 or 6 feet thick. For proofs of local violence accompanying the exhibition of the basalt, and many interesting details, the original Memoirs may be consulted.

The basaltic formation of Upper Teesdale in Yorkshire has been described by Professor Sedgwick, and its continuation through Northumberland by Mr. Hutton; and we can bear witness to the merit of their researches. The great mass of basalt (called Whin Sill) lies in a pseudostratum of most irregular thickness, enclosed among the strata of the carboniferous limestone series, generally in one particular part of the series, so that in the valley of the Tyne its place in the section is constant, and we think it occupies generally the same situation in Teesdale, though in Weardale another layer of basalt occurs. We cannot doubt that it was erupted from several local centres or lines, and that its thickness at different places was affected by their proximity to the eruptive channel. In the short space of six miles, from Caldron Snout to Hilton Beck, its thickness is diminished from 200 or 300 feet to 24 feet, and further South it disappears totally. But to the Northward the range is (interruptedly ?) continued to the sea-coast of Dunstanborough.

No dykes pass from this mass (in Teesdale) into the rocks above or below; so that a first view of the case suggests the belief that it was poured out as a mass of submarine lava upon the yet incomplete deposit of the carboniferous limestone. Professor Sedgwick, however, (*Camb. Phil. Trans.*) maintains that it was injected from below amongst these strata, and that it penetrated between the planes of the strata by violently uplifting them.

The strata in contact are affected by the basalt in several ways, which may be well seen about the high force. The subjacent shales are prismatized, so as to be mistaken for basalt, generally much debituminized, so as to become grey or whitened, and rendered brittle by condensation, but not much hardened. The sandstones are in several places highly hardened, rendered brittle and full of fissures, and much whitened. The limestones below the shale are remarkable for having their top bed full of iron pyrites. Those above, but not in contact with the basalt, are for a large tract of country totally changed from a full blue, hard, rather crinoidal limestone in the first degree to a pale blue, crystallized, soft marble, and in the extreme to a loose, granular, saccharoid rock, in which, nevertheless, some traces of organic remains (a crinoidal column) remain. But the most remarkable effect is the generation of garnets in the contiguous shale under the basalt of Cronkley scar; a case analogous to the one described in connection with the dykes of Plas Newydd by Professor Henslow. (*Geol. Trans.*)

The igneous rocks themselves are chiefly a fine-grained dark basalt, changing to a coarse-grained variety of the same ingredients. Contemporaneous veins of very beautiful hypersthenic and augitic trap pass through the basalt in several points, and it is traversed by a few productive lead veins.

The connection of several very remarkable and extensive basaltic dykes with this great "Whin Sill" is rather assumed than proved. In fact, there is no evidence of any one of these dykes being traced into the Whin Sill, and as some of them pass into the upper coal measures, and one divides magnesian limestone, lias, and oolites, we prefer to consider them of different Ages, though certainly related to the same local centre of igneous expansion. Successive injections of similar igneous rocks, at remote geological intervals, seem to be indicated by the phenomena.

These dykes pass in directions to the East North-East, East South-East, and nearly East, and the lines which they take are so straight through all sorts of rocks, their respective breadths, and the quality of the rock in each, so nearly uniform, though in these particulars they differ from one another, that, considering their extraordinary length, we may safely rank them as amongst the most remarkable phenomena of English Geology. The Cleveland or Cockfield dyke, in particular, ranges for seventy miles through the coal series, (where it chars the coal, hardens the sandstones, and debituminizes the shales,) the magnesian limestone, the lias shales and sandstones of the oolite series, which are affected like the coal system below. Generally it is a nearly vertical dyke, but at Cockfield fell is subject to oblique expansions of a singular kind.

The dyke which passes East North-East is remarkable for having a small vein of lead ore running by the South-East side of it, and for converting the shales through which it passes to the state of a soft, whitish shale, called pencil bed, like those in connection with the Whin Sill. It does not cut through the magnesian limestone.

Melaphyre, Pyroxenic Porphyry.

The history of this rock, which has a base of augite or pyroxene, holding crystals of felspar, is indissolubly associated with the name of Leopold Von Buch, who, by a series of observations, chiefly founded on a survey of the Southern flank of the Alps, has been led to form the remarkable opinions: 1. that the elevation of the Eastern range of the Alps, since the tertiary epoch, was contemporaneous with and dependent on the eruption of melaphyre; 2. that the dolomites of the Alps were produced from ordinary limestone at the same time and with the same dependence. The line of dolomites and melaphyres extends (interruptedly) from Bleiberg to Lake Lugano; but the occurrence of so many masses of dolomitic limestone in other situations than where melaphyre shows itself, must render inconclusive the inferences drawn from their connection in the Alps. Neither is this connection always very evident. On the contrary, even at Lugano, it is rather *near* the augitic rock than in contact with it that the limestone is dolomitized. Von Buch's own Map and sections (*Ann. des Sci. Nat.* tom. xviii. pl. vii.) would hardly lead to the opinion that the dolomitization of the limestone was especially due to the presence of melaphyre. For between the dolomite and melaphyre of the peninsula of Lugano, mica schist and another kind of porphyry intervene; and on Monte Argentera, the limestone which lies upon the melaphyre is not dolomitized. De Beaumont admits that it is even rare to find the dolomites near Lugano in actual contact with melaphyre.

It would, however, be unjust to Von Buch to reject the hypothesis on this account. He himself says it is to gaseous eruptions accompanying the pyroxenic eruption that we must ascribe the alterations of rocks.

The influence of these exhalations might be felt far from the main fissures occupied by melaphyre, and De Beaumont generalizes the phenomena so as to refer the production of dolomite to the exterior line of fracture of the primary rocks; that is, to the line which now divides the undisturbed from the disturbed rocks. See page 761.

The view is thus entirely changed, and certainly rendered more philosophical. Whatever may be its fate in this amended form, Geologists will have been taught by it to investigate generally what connection there may be between certain phenomena of alteration of rocks, certain lines of disturbance, and particular erupted mineral aggregates; and thus the field of research into the conditions of the local metamorphism of stratified rocks is greatly widened, and brought into nearer relation with the speculations concerning general alterations of the primary strata around granitic nuclei and axes of elevation.

Claystone.

In the cliffs of Corygills (Arran) are several claystone dykes. One of these slopes at a considerable angle through the sandstone cliff, and, being very wide, shows a columnar structure in the middle rectangled to the plane of the dyke; along the sides it is slaty. Between the columnar porphyry of Drumadoon and the Coves on the West side of Arran may be seen no less than five interpositions of claystone among the sandstone strata, mostly exhibiting a rude prismatic structure.

Near Tormore is the celebrated arched vein or dyke of claystone represented by Macculloch, and considered as composed of ellipsoidal concretionary layers by Boué. It is redder and softer in the middle than at the sides; it divides strata of red clay and white sandstone. Great variety of claystones occurs in the Pentland hills. (Professor Jameson, *Wern. Trans.* vol. ii.)

Claystone Porphyry.

Trachytic porphyry, (Boué,) clay porphyry, as it is termed by Jameson, occurs on the Western shore of the Island of Arran in considerable variety. It appears in the cliffs in huge overlying masses, and on the sandstone shores in dykes of great width. At Drumadoon many interesting exhibitions of it occur. We extract the following brief notices from a journal of observations in 1826.

A dyke (*a*) of clay porphyry 20 feet wide, ranging South 40° West, includes large modified felspar crystals, which are sometimes nodular in external figure. On the South-East side is a contiguous vein of greenstone. The porphyry encloses masses of greenstone; it is not prismatic. A huge mass (*b*) of clay porphyry, like a dyke or rather interposed bed, dipping South, has on the South a layer of more basaltic aspect, the two being united in one specimen. In the fine range of clay porphyry columns at Drumadoon, which are 60 or 80 feet high, occurs a dyke of greenstone passing in a line of double flexure obliquely through the pillars. At the base of these columns is a layer of more decidedly basaltic rock with few crystals of felspar, through which the same prismatic structure passes. Towards this great mass the dyke (*a*) tends, and is said to join it. A very wide dyke of clay porphyry, ranging North 60° East, (beyond the Coves,) has greenstone on each side, and also encloses greenstone.

Amygdaloidal Trap.

The Hill of Kinnoul, one of the most remarkable masses of trap rock in Scotland, rises near Perth, from out of the great area of red sandstones which lie against the primary strata of the Highlands. Its height above the plain of the Tay is stated by Macculloch (*Geol. Trans.* vol. iv.) to be 600 feet, and it shows precipitous faces to several quarters. The greater part of the hill consists of an amygdaloidal rock, whose basis varies from well-characterised basalt to wacke. The substances which impart to the rock its amygdaloidal character are, green earth, calcareous spar, quartz, and calcedony. Green earth, or chlorite, occurs in nodules generally small and round; it also invests the roundish nodules of calcareous spar, which are crystallized within but externally accommodated to the shape of the cavity in the rock, or to the crystals of quartz which sometimes line the cavity. The spar is sometimes crystallized at liberty in a cavity of quartz or agate.

The quartz is found to vary by several shades into agate and calcedony, which latter sometimes appears in a stalactitical form hanging downwards in the cavities of the amygdaloid. Alternating zones of quartz and calcedony sometimes appear in the same nodule; amethystine quartz also occurs, and we have in Kinnoul almost every variety of angularly zoned agates. Veins as well as nodules of calcareous spar and quartz divide the rock, and more rarely sulphate of barytes, chert, and agate. Veins of heliotrope have also been found, but without the red spots. Macculloch thinks there is not the least reason to doubt that the substances now filling the cavities of the amygdaloid have been introduced at some period since the cavernous aggregation of that rock from a state of lava.

Shales and sandstones are hardened and altered, and much confused at their junction with the trap. A remarkable case of seeming prolongation of thin masses of the shale into the substance of the trap, so as to resemble veins, is described and represented by Macculloch. (*Geol. Trans.* vol. iv. pl. xi.) In these seeming veins the laminated texture of the schist disappears.

Alternations of amygdaloid and sandstone are frequent about Oban.

Wacke.

Respecting this softest of the trap rocks we shall only observe, that in the Calton Hill, Edinburgh, it forms part of those variable masses, which sometimes may be called amygdaloid, sometimes porphyry, and not unfrequently assume the aspect of breccia; being likewise traversed by numerous small veins or strings of calcareous spar. In the superior and Eastern parts of this hill wacke alternates with bituminous shale and nodules of argillaceous ironstone, in many repeated strata dipping to the East. At the surfaces of junction there sometimes appears a gradation from one rock to the other; and it does not appear that any decided marks here occur of the action of heat upon the shales.

Pitchstone.

As before observed, pitchstone occurs in the Isle of Arran both in dykes and interposed beds among the sandstone strata. The Western coast is particularly interesting in this respect. The same cliffs which exhibit so many claystone masses alternating with sandstone, contain also parallel short bands of pitchstone probably connected with the neighbouring dykes. One of these dykes, about 30 feet wide, is curiously mixed with hornstone, and for the most part bordered along the sides by greenstone. The disposition of these substances in the fissure will be understood by reference to the horizontal plan, pl. vii. fig. 10, where the letters H, P, and G are placed against the hornstone, pitchstone, and greenstone, respectively. The pitchstone is generally of a dark green colour, fissured longitudinally into rude prisms, which are jointed transversely at about two feet distance, or concreted into smooth conical masses. It seems to pass gradually into the hornstone, which is laminated parallel to its bounding surfaces. The dyke appears in one place to deviate from its vertical course and to go under a portion of the sandstone. A greenstone dyke, which is nearly right angled to the course of the pitchstone, is shifted by it.

In another dyke, one side is yellow pitchstone closely approximating to claystone, within this light green and red stripy pitchstone, then silicious splintery stone in irregular masses, (hornstone,) and the opposite side is greenstone. Another of these curious dykes is green pitchstone on each side, then red pitchstone, and in the middle dark grey hornstone.

The pitchstone bed at Corygills is 15 feet thick, and a dark green or black rock, enclosed between strata of sandstone, which are hardened towards the junction. The pitchstone is marked by lines parallel to its nearly level surfaces, and these are crossed by the smooth distant vertical faces of prisms. The lower part is porous; between it and the sandstone beneath is a white crumbly or fragmentary mass soft as steatite, which it much resembles.

Trap Tuff.

Porphyritic Breccia. "Volcanic Sandstone."

Re-aggregations of the disintegrated or fragmented materials of trap rocks are generally known under the vague name of trap tuff and compared with volcanic tuff, sometimes without much reason. Amongst the slaty rocks of Cumbria, in Glen Coe and Ben Nevis, fragments of felspathic and porphyritic rocks are frequently found united into a solid breccia; under Arthur's Seat and in the Calton Hill recomposed irregular strata, chiefly derived from fragmented rocks of igneous origin, appear associated with ordinary greenstones, porphyries, and basalts. In many instances these have no just claim to be ranked with the pyrogenous rocks, but should be transferred to the class of tumultuary and local aqueous deposits: the circumstance that the principal portion of the ingredients is of *igneous origin*, is not probably confined to these rocks, but is often, perhaps with truth, ascribed to the whole mass of sedimentary deposits from water.

In the vicinity of Oban, in juxtaposition with some interesting amygdaloids and altered shales, sandstone beds, composed of the grains of disintegrated trap rocks, are found resting on conglomerate, amongst whose pebbles are granite, porphyry, quartz, red and white amygdaloid, fine-grained basaltic trap, sandstone, jasper, &c.

Mr. Murchison has recently found, along the South Wales border, many examples of the occurrence of sandstone composed of the ingredients of trap rocks. A little removed from the steep slopes of the Wrekin and Caer Caradoc, rocks of this kind occur in beds, and contain organic remains, but in all respects of composition strongly resemble greenstone. This was noticed by Aikin. At the Southern extremity of the Wrekin, the stone is of a dark green colour, and is evidently composed of the ingredients of greenstone and syenite with a few scales of mica. Near the Caradoc these beds contain much decomposed felspar. They are part of the 4th system, p. 568, of the fossiliferous greywacke of Wales, and are attributed to submarine eruptions of volcanic substances in such a state of disintegration as to mix with the sea water, and be diffused over considerable breadths of the bed of the sea.

SECTION 4.

Mineral Veins.

The circumstances attending the occurrence of mineral veins in the rocks, their intersections with each other, and the arrangement of their mingled metallic and sparry contents, have been sufficiently studied to ascertain that these valuable elements in the adaptation of our Planet to the wants of its inhabitants have been subjected to a great variety of processes depending possibly on one general law, but greatly modified both in combination and energy by local and periodical conditions. In the vague language of imperfect Science, we say, many *causes*, separate or variously combined, have been concerned in the production of mineral veins; and it is probable that the most advantageous mode of investigating their origin, consists in the attempt to infer from the mass of facts already brought together, what are, respectively, the spheres of action and limits of intensity belonging to the several processes concerned; and afterwards, from a more general contemplation of these processes in their various degrees of combination, rise to a comprehensive notion of their connecting laws and general cause.

This is not the mode usually followed by writers on mineral veins. Neglecting the general fact of the complication of the phenomena, they have been mostly anxious to try their bearing individually, or in mass, upon the perfectly general question of igneous or aqueous agency, and thus nothing was explained. A vast abundance of minute information on veins has been irrecoverably wasted; and the experienced miner laughs at the reasoning of the half-informed Mineralogist, contemptuously rejects his theory of veins, and contents himself with believing that the facts are inexplicable. This dissociation of observers and reasoners is the true cause of the comparatively small advantage which has been derived to Geology from the immense and various mines of the British Isles; on the one hand we have the greatest possible variety of phenomena, on the other the full extent of the resources of chemical and mechanical philosophy, but these have not been combined. If the zoological principles of Geology are better established and more fertile in deductions than the mineral principles, it is not because our knowledge of organic nature is more advanced than the science which treats of the constitution and agencies of inorganic matter, for the contrary, perhaps, is true, but because in the one case the ancient effects and the modern laws of action have been brought into mutual illustration, in the other deprived of all connection.

In order to prosecute the investigation according to the principles which we have stated to be the best, we must limit our inquiry to those subjects most distinctly connected with metallic accumulations in the rocks. To support inferences concerning the general laws of processes which have produced mineral veins, we may with great advantage include the history of basaltic and granitic, and porphyritic dykes, but for the discovery and estimating of the processes themselves only those effects must be examined in which they are especially concerned.

Though in some instances the distinction between rock dykes and mineral veins be imaginary, they are in general clearly contrasted by the nature of the substances which they contain: in the former case, crystallized minerals of the same kind as those great interior masses of consolidated rock from which they often are evidently ramifications; in the latter metallic substances which are not known to exist in nature except in these situations and in other very similar or distinctly related to them by position, and crystallized or earthy minerals, seldom of the same kind as those which occur in any of the rock dykes. To this general rule quartz is one of the most striking exceptions; yet even in this instance it is remarkable that the quartz of veins is of a very different aspect from that mingled with the ingredients of granitic and trap rocks. We must therefore take the presence of metallic matter and certain nonmetallic substances usually connected therewith, and commonly called veinstuff, as the leading characteristic of the mineral veins whose history we are now to examine, and connect with these all other cases of metallic aggregations or occurrences of the vein-stuff which seem referrible to the same or analogous processes.

This view embraces the following points of research. 1. What substances are found in mineral veins and repositories. 2. The manner of their aggregation or mixture. 3. The situations of their occurrence. 4. The relations between frequency, arrangement and contents of the veins, nature, age, and position of the rocks in which they occur.

Substances in the vein.

What substances, &c. The simple minerals which occur in veins and analogous situations, are far more numerous than those which are found as component parts of the rocks. Igneous rocks, and especially those of modern volcanic origin, hold a very great variety of nonmetallic substances, some of which also occur in veins; but it is almost exclusively in this latter that we are to seek the metals in their pure state, alloyed with one another, or mineralized by combination with sulphur and other combustibles, with oxygen, chlorine, and other gases, or converted into salts by union with various acids. Every elementary substance yet discovered by Chemists exists in the earth, and it is probable that none of these are entirely absent from the solid contents of mineral veins; though this has not yet been shown to be the case for iodine and bromine, which seem universally present in the modern ocean, and azote, which appears in an especial manner devoted to the atmosphere and to the organic portion of nature.

Alloys. The metallic substances seldom occur pure, sometimes in alloys, similar for the most part to those now producible by the Chemist, as silver, antimony, cobalt, nickel, iron, with arsenic; silver and nickel with antimony; lead, gold, silver, and bismuth with tellurium; silver with mercury; platinum with gold, &c. The only known circumstances which stand as antecedents to the production of such alloys, is heat, produced by either chemical or electrical action; and perhaps there is no *single fact* connected with the theory of veins, on which the conclusion of the influence of heat in their production might be more securely based. The rarer occurrence of *pure* metals affords an argument perhaps of less force, but perhaps we may draw the same inference from the very numerous class of metals mineralized by union with combustibles, as sulphur, phosphorus, carbon, selenium, &c., to the formation of which, according to the state of our knowledge of chemical forces, heat would appear to be directly necessary.

Comburets.

Oxides and salts. We cannot apply this general argument to the case of the metallic oxides which are very prevalent in veins, because, in the first place, these are produced under various relations to heat, moisture, and contact with gaseous substances; and, secondly, have various degrees of permanence when exposed to high temperatures, either separately or combined. Neither have we any general conclusion to present concerning metallic salts, which likewise are not rare in veins, since these are also in the same way various in their origin and degree of permanence. There is besides a difficulty attaching to this branch of the subject arising from the interesting fact, that, in very many instances, metallic oxides and salts are derivative compounds from sulphurets and other primary combinations; and when this is very evidently the case, they are called epigene. This may be said to be even frequently the case with oxide of iron, carbonate of copper, and probably carbonate, phosphate, and other salts of lead.

Nonmetallic minerals. Besides the metallic ores which impart to many veins their most striking, if not most constant characters, various earthy minerals lie in these repositories, and, as will afterwards appear, under certain definite relations to the enclosing rocks as well as to the included metals, and with a less distinct dependence on the local situation or *mining district*. These earthy substances are usually called the gangue, vein-stuff, or matrix of the ore. Generally they are crystallized, as quartz, fluor spar, calcareous spar, phosphate of lime, the sulphate and carbonate of barytes, strontites, &c.; sometimes appear massive, as quartz and several other minerals when the vein has no cavities in it; and sometimes the vein-stuff is entirely soft argillaceous matter, of different aspect in different mining districts. We are not aware that these soft kinds of vein-stuff have ever been analyzed, though probably some curious results might reward the labour. The Cornish mines would furnish many examples.

Rider. In some veins, masses of the neighbouring rocks are enclosed and penetrated to a great extent by little *strings* of the ore and spar, so as occasionally to be worth the trouble of working. The vein is said in this case to bear a rider. It, in fact, sometimes becomes under these circumstances a double vein: more rarely pebbles and other marks of watery action, are stated to occur in soft veins.

Mode of Aggregation of the Ingredients.

In this respect there is a variety of appearances which deserve especial notice as indicating some of the conditions under which the vein was filled. In some cases, for instance, the whole breadth of the vein is occupied by one kind of substance, as lead ore, or quartz, or sulphate of barytes; in other instances, the metallic matter is interspersed in small masses through a general basis, as quartz; but, generally, the different substances which fill the vein are ranged in a definite order of succession from the sides of the vein toward the middle, in which, commonly, the metallic matter occurs in an irregular vertical table called a *rib of ore*. These variations are best observed in the proper veins, but are also to be noticed in the *nests* and detached masses of ore and vein-stuff which sometimes occur in the vicinity of the veins.

General idea of mineral vein.

The *ordinary* notion of a mineral vein is well exemplified in some Derbyshire specimens, not rare in collections, which, when cut across, show in the middle masses or a continuous rib of galena, and on each side of this, to the extreme edges of the mass, (or narrow vein,) layers of fluor spar and carbonate of barytes in frequent alternation, all the materials being crystallized together without leaving any cavities, yet preserving their own character of structure.

Thus, in the diagram, pl. vii. fig. 11, *a* is the middle rib of galena, *b b*, *c c*, the alternating bands of barytic spar and fluor spar; *d d*, the masses of rock which enclose the vein, are called the walls or cheeks of the vein.

Supposed successive deposition of the substances.

The contemplation of these specimens seldom fails to impress upon the mind an imperfect conviction that the several bands of mineral substances were deposited on the cheeks or walls of the vein in succession, the middle being filled last of all; and this theoretical notion has been illustrated by comparing a mineral vein to a narrow gallery whose walls were covered by many successive coats of plaster of different colour and composition. Werner adopted the notion of the unequal antiquity of the vertical layers of the vein so implicitly as to speak of the middle ribs as always of less antiquity. It is difficult to resist this impression, especially when, in addition to the circumstance of the succession of the laminæ, we observe that these laminæ are so crystallized as to turn their free terminations towards the centre of the vein, and in that direction to imprint the next layer with their own forms, just as crystals forming in a vessel shoot their points toward the part still remaining liquid, and in that direction are covered by the subsequently formed crystals. Very similar inferences are suggested by certain agates, and more distinctly by geodes in basalt, and the crystallized cavities in limestones, in the interior of shells, &c.; in which cases the hollow towards which the crystals pointed still remains.

Reasons against this notion.

Yet this first impression loses much of its force when, instead of confining ourselves to a cabinet specimen, we examine the whole extent of a mine; for here in the first place it is very often found that the regular succession of minerals from the side to the centre is a limited though repeated phenomenon; that the rib of ore is of short horizontal, and sometimes still shorter vertical extent, diminishing to nothing, or diffused in small grains through the contiguous spars; that different metals are found in the same vein at different depths and at distant points along its course; and that both the quantity of metal and the presence of spars are dependent on the hardness, and perhaps on some properties imparted by the chemical nature of the rocks which the vein divides. Instances of this will be given hereafter.

Chemical reasons.

The phenomena of crystallization before alluded to can hardly be thought to prove the successive introduction of the mineral laminæ into the vein; though very probably they do demonstrate the order of crystallization of these substances.

In some cases we observe indications that one kind of mineral has been formed round another as a nucleus; as for example, sulphuret of copper round icosaëdral iron pyrites in a part of Caldbeck fells, Cumberland, and more frequently in many places carbonate of copper and carbonate of lead round the sulphurets of those metals. It is very often the case that the metallic matter of the vein is collected into the middle and forms there a distinct tabular mass, called a rib of ore, more rarely it is disseminated in the gangue. Generally, only one kind of metal abounds in the same part of the vein, but the same vein may yield lead above and copper below, copper above and tin below, or lead in one place and copper in another. The observation is frequent that ore is collected into certain vertical portions of a vein which are worked above and below level, and between which little but vein-stuff is found in the horizontal drift. There is a vague notion amongst miners, that veins are most productive in the deep, and it is at least probable that they are less rich near the surface.

Association of minerals.

Werner insists on the fact, that certain associations of minerals can be traced in veins. He notices the concurrence of lead glance, and blende or calamine, and copper pyrites; of cobalt, copper, nickel, and native bismuth; of tin, wolfram, tungsten, molybdena, and arsenical pyrites; of topaz, fluor spar, apatite, schorl, mica, chlorite, and lithomarge; of brown ironstone, black ironstone, manganese, and heavy spar. He says where tin occurs, ores of silver, lead, and cobalt, heavy spar, calcareous spar, and gypsum are rarely found. Cinnabar and other ores of mercury scarcely ever occur with the ores of other metals, except iron ochre and iron pyrites.

Rolled and fragmented masses.

That fragmented masses of the neighbouring rocks should be found in mineral veins, cannot be thought surprising. It is a common occurrence in mining districts, both of primary and secondary rocks. Thus gneiss at Joachimsthal, clay slate in Cornwall, limestone in Cumberland, are included in the veins. A more remarkable case is that of *rolled* masses lying in the veins. Werner mentions a vein in Danielstollen at Joachimsthal, fourteen inches wide, which, at one hundred and eighty fathoms depth, was almost entirely composed of rolled pieces of gneiss, some of them nearly spherical. In the Stoll Kefier, near Riegelsdorf, a vein of cobalt was cut through by another vein of sand and rolled pieces. These examples seem satisfactory, but we must always be careful to discriminate between rolled pebbles and concretionary masses.

General forms of veins.

Mineral veins are usually distinguished by miners into several kinds, according to their general form and direction, because these circumstances are the most influential in the arrangement of their works. *Rake veins*, the most common and characteristic, may be considered to fill long, narrow fissures, which pass in a vertical or highly inclined direction downwards from the surface through a great thickness of the subjacent rocks, whatever these may be, and preserve nearly the same angle of inclination and the same linear direction through their whole course. *Pipe veins* are also highly inclined, and pass downwards in the same manner, but they rather resemble irregular chimneys than fissures, and are subject to great swellings and contractions of their diameter. They sometimes pass downwards along the surfaces, and in other cases penetrate through the substance of the strata. The mines in the neighbourhood of Ecton, in Staffordshire, are on pipe veins. Perhaps we may give the same name to the irregular cavity of copper ore, which forms the celebrated Parys mine in Anglesea, and to the iron mines of Dannemora, in Sweden. *Flat veins*, or *streaks*, as far as we are acquainted with them, seem hardly to deserve a special name, being only portions of rake veins which have been changed in their inclination, and made to pass for limited distances parallel to the beds. In the limestone districts of the North of England, this happens principally in connection with certain limestone beds. Williams has a title of *Gash veins* to express such as range for considerable lengths, like rake veins, but are wide at top, and grow narrower downwards, till they entirely vanish. This is a rare case; though Werner's opinion seems to be that many veins grow narrower downwards.

Strings.

Perfect parallelism of the sides or walls of a rake vein, which is the most regular of all, is a rare phenomenon. Most commonly, indeed, there is a definite boundary to the mineral masses presented by the rocks on each side, but this is only on the great scale; and the operations of mining disclose to us innumerable cracks and fissures in these boundary walls, which, when filled by metallic or spongy matters, are called strings, and are frequently worth the labour of following even to great distances from the parent vein, if, indeed, we are entitled to use this hypothetical expression. The notion of miners generally appears to be, that these strings are to be viewed as *feeders* of the vein, and in proportion to their frequency in many instances, is the productiveness of the vein. In the accompanying diagram, pl. vii. fig. 12, the vein *v*, *v* is represented as sending out small branches or strings into the neighbouring rock. A rock thus penetrated by strings is sometimes said to be *ridered*, just as the masses which are often included in the vein, and the walls which bound it, are called *rider*. In many rocks these ridered parts are very greatly altered from their original state.

It sometimes happens that, in passing through rocks of various hardness, as limestone, shale, &c. the veins turn flat for a short distance on the hardest and most connected beds, (as, for example, on the Tyne bottom limestone of Cumberland,) and afterwards continue their course. These flat parts usually send off strings into the limestone, which may thus be ridered to a considerable distance.

Disseminated veins, &c.

Sometimes the mineral is disseminated through the parts of the rock adjoining a vein, or collected in small nests and other closed cavities. This happens not only in the Cornish mines, in killas and granite, but in those in the mountain limestone tracts of the North of England, and even in magnesian limestone. Generally speaking, we may be sure that this metallic impregnation is so related to the veins, that it is an effect of the same agent. Whatever filled the veins, also transferred to small distances from them some of their constituent minerals. Certain metals and ores are more liable than others to this lateral diffusion. Native silver, silver glance, red silver ore, native copper, tin ore, iron pyrites, and red iron ochre, are specially noted by Werner as occurring in this way. He says, copper ore, pyrites, and lead glance seldom exhibit this effect. The assertion may be disputed as to galena, which is found as well as blende, and bitumen, and calc spar, and quartz, in closed cavities of shells, in mountain limestone, and in other strata.

Tin floors, stockworks, &c.

The dissemination of tin ores through some of the rocks of Cornwall, is noticed by Mr. Hawkins, under the title of Tin-floors. (*Geol. Soc. of Cornwall Trans.* vol. ii.) He observes, that the whole tenement of Botallack is said to be full of tin floors. At Zinnwald, mineral beds or floors have long been the object of mining adventure. There granite alternates with the tin floors, which consist of quartz and mica, with tin ore, fluor spar, and wolfram, quartz and mica with tin ore, &c. At Breitenbrünn a floor of this kind has been very extensively worked in a gneiss rock.

The stockwork of the German miners is to be considered as a mass of rock impregnated with metallic matters, in numerous small veins, which come together irregularly, so as to make particular parts extremely rich. The working of such mineral repositories is directed by quite other principles than those which serve for straight veins of definite magnitude. The stockwork is generally opened like a vast quarry, and the excavations are prosecuted irregularly in the most favourable directions. Perhaps the copper mine of Parys mountain in Anglesea, the iron mine of Dannemora in Sweden, the tin ore mine of Geyer in Saxony, are examples of immense stockworks. Werner, however, appears to have considered the stockwork as peculiar to tin ores.

Relations of Veins to each other.

The influence which veins exert on each other may be in some measure ascertained by an examination of the phenomena at the points where they come into contact or cross each other. At these points it is very often found that the quantity of ore is suddenly increased to a large amount, and for some distance, either in one or both of the veins. Many veins are productive only near such points, or yield there peculiar ores and minerals. This does not depend upon the enlargement of the vein merely, but is one of many facts which appear to indicate the agency of certain electric attractions in the disposition of the materials of mineral veins. We have heard miners say, that in certain cases neighbouring veins are subject to a kind of reciprocity, so that they are not both productive in the same ground, but where one is rich the other is poor; but this cannot be established without a very large collection of instances carefully observed.

Age of veins.

The intersections of veins likewise furnish us with another well-ascertained class of facts, which throws light on the relative epochs of their production, independent of the evidence on this subject furnished by the rocks which they divide. When two veins cross, it almost invariably happens that one of these cuts is continued right through the other, as a wall is sometimes continuous through another wall of brick from top to bottom. Thus, a vein of copper ore may cross and cut through a vein of tin ore, a vein of lead ore may cut through a vein of copper ore, and all these be cut through by some other sparry vein or porphyry dyke. It is supposed, by almost every writer on the subject, that the relative antiquity of the veins which thus intersect one another may be immediately determined; and that in every case the vein which is cut through is the oldest of the two. Werner took this as the basis of his classification of veins, and most practical as well as theoretical miners agree in his views; but they are nevertheless controverted upon various grounds, and as the question is of great interest, it will be useful to present a short connected view of the facts bearing upon it.

We cannot make a step in this argument, except upon the admission that the veins are posterior to the rock which encloses them; in other words, that the space in which the mineral masses of a vein lie, once existed as a fissure in the rocks, and was subsequently filled up by the accumulation of the sparry and metallic matters. This is generally supposed by authors to be a self-evident proposition. It is equally allowed by the Wernerian and Huttonian hypotheses; and practical miners can with difficulty be made to understand that any doubt has been entertained on what seems to them so plain a truth.

Phenomena in Cornwall considered.

But the embarrassing phenomena of the granitic and mineral veins in Cornwall have created amongst some of the Geologists of that district a strong suspicion, that veins are not to be pronounced of different antiquity on account of the circumstances of their intersection, nor to be considered as filling fissures at all; but that the veins and the rocks which enclose them are of the same origin. Even the common fact of veins passing through slate into granite, does not appear to them subversive of their views, which would reduce to one epoch and one origin the most dissimilar chemical and mechanical phenomena. This insulated opinion has been generally neglected, as opposed to the actual state of knowledge and inference on the subject, but as it undoubtedly contains at least a portion of truth, we shall trace a few of the circumstances on which it is founded. Those who favour the opinion in question, must not be surprised at our omitting altogether what may perhaps appear to them the strongest argument of the whole, *viz.* the mechanical difficulties attending the generally received view, that veins were originally fissures of the rocks, because these difficulties have been in some cases surmounted, and in the rest are certainly more than balanced by others of a different kind affecting the Cornish theory. It is, besides, no argument for one theory that another is beset by difficulties which are left unexplained in both.

In the neighbourhood of a vein.

1. It is a general fact, that the walls of a vein partake in some degree of its characters, and that effects, apparently depending on the vein, propagate themselves into the neighbouring rocks. Thus the walls become more indurated, more crystalline, and for considerable distances are filled with the matters of the vein; and even the very substance of the rocks is impregnated with mineral combinations. In a Country where the veins are numerous, large masses of the rocks may in this way be *ridered*, as it is termed in the North of England; and if such a gradation of characters could be relied on as proof of contemporaneity of origin, this may in a few cases lead to the conclusion, that the veins and rocks are coeval.

But what is the true conclusion on this point? Is it not that these effects are locally related to the veins, because they are a consequence of their influence, or rather of the agency which occasioned them? That the ridering of the neighbouring rocks is coeval with the production of the vein may be allowed; but because these rocks are clearly defined from the veins, and fragments of them are enclosed in the veins, and the mineralizing influence which they have suffered obviously depends on the influence of the veins, we cannot hesitate to admit that these latter are of separate and subsequent origin. These facts are similar to what occur in other mining districts, where the stratification and consecutive depositions of the rocks divided by veins is perfectly evident, and where, therefore, contemporaneity of the veins is impossible.

In different rocks.

2. It is found, that when veins divide different sorts of killas or other rocks, that their contents vary in some inconstant manner, according to the nature of the rocks; and, therefore, it has been sometimes argued, that the production of the one is dependent on the other. The most usual notion on this subject is, that the veins may be viewed as secretions from the rocks; and by some this is supposed to have happened after the production of fissures; by others, by a mere internal separation of the parts of the mingled metallic and earthy mass.

This notion of the slow separation of the ingredients of rocks is in accordance with the principles and facts of Chemistry, and must be often appealed to, if we would explain by *true causes* the phenomena of mineral veins; but with respect to the question before us it is indecisive, and may with equal propriety be applied to veins of fissures and veins of segregation. The same electric attractions between certain minerals in veins, and certain rocks about them, obtain in the secondary strata, as in the slates and granites of Cornwall; but if the preexistence of fissures in the former is certain, why shall we deny it in the latter?

Contemporaneous veins.

3. There are combinations of minerals in masses of various figure, which, upon very good grounds, are admitted to be contemporaneous with the rocks in which they lie; and if we choose to call by the name of veins all such distinct combinations of minerals, these certainly are contemporaneous veins. When in granite, greenstone, &c., we find particular portions either linear, tabular, globular, or in any other figure which have a different proportion of ingredients from the other parts, and in consequence become conspicuous and distinct, except at the edges, which graduate without any sign of fissure into the ordinary mass of the rock; these may certainly be pronounced contemporaneous veins, and they have been produced by a process of secretion or segregation during the crystallization of the rock. These cases are perfectly distinct, and by contrast place in still more striking light the true relative age of veins of fissures.

In some instances veins of calcareous spar or other minerals lie *wholly included* in limestone masses, and these are properly called veins of segregation, but they are *not contemporaneous veins*, for they have clearly been fissures filled at some period since the consolidation of the rock, and the proof is, that shells, corals, &c., are split and sometimes displaced by these sparry veins, which undoubtedly occupy cracks left by the shrinking of the rock in the process of consolidation.

Upon the whole then, allowing every just latitude to the doctrine of contemporaneous veins, we must admit that the greater number of veins are posterior to the rocks which enclose them.

Intersection of veins.

This granted, we may return to the intersections of veins. The most simple case is when two straight veins cross without any change of direction, or any lateral displacement; and the order of effects appears to be the production of a fissure, and the filling of this by a vein, which was afterwards broken through by another fissure, and this, in its turn, received another mineral vein. It seems difficult to doubt the truth of this explanation; for if the vein which cuts through the other be subsequent to the fissure in which itself lies, it must also be subsequent to the vein which that fissure divides. The occasional complication of the problem by the number of intersections does not at all change its nature.

Appearances at the crossing.

There are, however, two things to be attended to, which require further consideration. It is sometimes observed, that the vein which upon this theory is the oldest, suffers a particular kind of accident at its junction with the other. It is divided into several branches on one or both sides of the cross veins, and these branches enclose portions of the neighbouring rocks. There is some difficulty in this case however it be considered, and we must demand more exact accounts than are usually met with of these facts before attempting to reason upon them. The coincidence of this splitting of a vein with the crossing of another vein, may often be only accidental; for such splitting frequently occurs in a wide vein, far from any cross course.

The fissures which have received the mineral veins are in most cases accompanied by slips or dislocations of the strata in a vertical direction, and the veins are of course subject to the same accidents of displacement. When two veins cross, and both are vertical, the lines of bearing of the two portions of the displaced vein must remain coincident after the fracture; if the divided vein be not vertical, its separated portions will have their lines of direction parallel, but not coincident; and in any horizontal plane they will *appear* to have sustained a lateral movement. Thus in the diagram, pl. vii. fig. 13, the cross vein *a* and the divided vein *b* are both vertical, but the divided vein *c* is inclined in the direction of the arrows, and its *apparent* lateral displacement is really due to a vertical movement. If two divided veins are inclined in opposite directions, and be dislocated by the same cross vein, they will appear to have moved laterally in opposite directions, as *c* and *d*.

Were we to include the cases of the inclined cross veins, and also those where the inclination of these veins varies both in amount and direction, the results would become too complicated for explanation without mathematical symbols; and we must, besides, remember that the displacement of the strata is really very seldom in a vertical direction, but generally accomplished by an angular movement from some fixed point, or round a virtual centre. We must, therefore, be very slow to admit the difficulty of the problem of the displacement of the solid masses of the earth as an argument against the received opinions concerning mineral veins, for this principally depends on the want of precise and sufficient data.

Several remarkable cases which occur in the mines of Cornwall have been simply explained by Mr. Lonsdale, and there can be no doubt that the application of the principles of solid geometry to other complicated phenomena of that interesting region will gradually remove much of the mystery which has been supposed to hang over them.

Geographical relations of Veins.

Though, properly speaking, there is no real connection between mineral veins and the external physical configuration of the earth, yet, as this configuration is connected with peculiarities of internal structure, it is generally found, as Werner long ago indicated, that mining districts are almost entirely confined to the vicinity of mountains or elevated land, because in those situations the rocks were most dislocated by slips, and divided by fissures at the period of their elevation. It is not the absolute height of the ground, but the circumstance of its having been much exposed to subterranean convulsion that determines the prevalence of mineral veins. The rich mines of Cornwall are in comparatively low situations, but they are all in the vicinity of erupted and elevated rocks.

There appears to be no limit either of height above or depth below the sea, which defines the productiveness of veins, though in some Countries the higher, and in others the lower situations are most favourable.

It is sometimes found that the contents of a vein vary with the depth, without any particular geological conditions; as for instance in Cornwall copper is prevalent in the mines at greater depths than tin, and in the slate tract of Cumberland veins which bear lead near the surface yield copper in the deep. In other cases there appears a peculiar determination of the metallic ingredients to particular situations. The mines about Ecton yield copper; those of Derbyshire generally lead; in the Penine chain the veins generally yield lead, but toward the Eastern and Western limits of the district copper becomes less uncommon.

The length of a vein of fissure is perhaps hardly in any case certainly known; because when it ceases to be worth working, it is for all the ordinary purposes of mining said to be dying out, or cut out, or ended. The richest veins are productive for limited lengths, but the fissures which they fill may be, and are often extended far beyond the spaces occupied by metallic impregnations. Some of them are known to extend, and to be productive for many miles in the Harz, in Cornwall, and in the North of England. The width of veins is various, in different veins, but generally nearly constant in the same vein. A width of twenty feet is very unusual; most veins are less than six feet wide.

Directions of mineral veins.

There is a peculiar geographical relation of veins which is very difficult to understand, but which is so general that it may eventually be of the greatest value in correcting and perfecting our theories concerning them. This is the general *direction* of the veins. The most general direction of the great dykes and faults in the North of England, may perhaps be defined to be nearly East and West. But this is much more certainly true with respect to the mineral veins of the limestone districts of Weardale, Allendale, Alston Moor, and all the mining districts of Yorkshire; and it is equally recognised in the primary tracts of Cumberland, Westmoreland, and Lancashire. This is so general a fact, that the East and West veins are called right running veins, while the few which range more nearly North and South are called cross courses. These latter are seldom rich in metal; they often cut through and shift the right running veins laterally, as both of them shift the strata vertically. There is often to be observed a sort of compensation in the dislocating effects of veins. In Weardale most of the veins throw up to the North, while the parallel courses in Allendale and Alston Moor throw up to the South. The lead veins of Flintshire and Cardiganshire have the same East and West direction, and so have those of Mexico.

The lodes and veins of Cornwall are most generally

East and West veins, or nearly so; and these, according to Mr. Came's (*Trans. of Geol. Society of Cornwall*) excellent Memoir, the *oldest veins* in that district, being traversed by the oblique veins and by the cross courses elvans and flukans. But not all the East and West lodes are of the same age, the tin being older than the copper; neither are all the East and West tin veins of one age, for those that underlie to the North, are generally traversed by them that underlie Southwards. These curious generalizations are not to be overthrown by particular discordances; their value may one day more fully appear, and they are certainly supported by analogous though less varied occurrences in other Countries.

The general order of their dates may be thus expressed.

Directions of veins of different antiquity.

1. Oldest, East and West, tin veins underlying to the North.
2. East and West, tin veins underlying to the South.
3. East and West, copper veins generally East 10° South.
4. Oblique or *contra* copper veins, generally East 30° to 45° South.
5. Cross courses not metalliferous, North and South.
6. Copper lodes of more recent date and lead veins.
7. Cross flukans or clay dykes nearly North and South.
8. Slides in all directions, but generally East and West.

The porphyritic and other dykes called elvan courses, are very generally divided by the veins, and seem to be of greater antiquity.

Werner has observed this geographical relation of mineral veins, and states the two following cases. In the mining district of Freyberg are two classes of veins very different from one another. One of these classes consists of veins which run from North to South; the veins of this contain lead glance, black blende, iron, copper, and arsenic pyrites, quartz, and brown spar. This is the oldest vein formation. The second class of veins which always traverse the former, and are never crossed by them, contains lead glance, radiated pyrites, heavy spar, fluor spar, and quartz; they stretch between the sixth and ninth hours of the mining compass (East to South-East.)

The mining district of Ehrenfriedesdorf, contains veins of tin and silver glance. The tin veins are always traversed by the silver, the direction of the first is between the sixth and ninth hour, (East and South-East,) that of the last from the ninth to the third hour. (South-East, South, South-West.)

Another geographical relation.

There is observed in some mining districts another remarkable relation of metalliferous veins to geographical lines. Though in the North of England the most frequent direction of the *veins* be East and West, the *mining districts* seem rather to be ranged in lines from North to South. The nature of this relation will be more easily understood if we add that both in Cornwall and in Cardiganshire, where the veins are also most frequently East and West, Mr. J. Taylor has observed lines of greater productiveness ranging nearly North and South, across the bearing of the veins. These curious notices suggest the inquiry whether the lines of productiveness are dependent on any principal axis of dislocation or on the occurrence of cross courses. The former case seems to be vaguely indicated by the phenomena in the North of England; perhaps the latter may be more applicable to Cornwall.

Connection of Fissures and main Joints.

The remarks on the joints of rocks in p. 543, 544, may be referred to as sufficient to show the importance of studying their direction in connection with that of the fissures of mineral veins. It is certain that in the limestone dales of the North of England, mineral veins are sometimes directed along the master joints of the rocks, also that in the slate tracts, veins and dislocations range along the cleavage planes of the slates. (Craven.) Dr. Boase has noticed the same thing in the slate tract in Cornwall, and such observations will doubtless be multiplied. Mechanical considerations might have led us to anticipate this result; for the main joints and cleavage planes would often be the lines of least resistance and yield more easily than other parts to any eruptive or depressing force applied to the planes of stratification. The direction of the master joints is certainly definite over large tracts of country, and if we should find eventually that mineral veins have commonly taken the same course, their regularity will no longer be an argument against, but an additional evidence for the vertical movement of the masses.

Relation of Mineral Veins to the Rocks which them enclose.

The relation of mineral veins to the rocks which enclose them offers a wide field of inquiry, which has been much studied, and yet is very little understood. It is difficult to distinguish clearly between the *accidental* and the *necessary* association of the phenomena of veins and rock masses; it is perhaps hardly possible at present to form a satisfactory opinion as to the amount of effects produced by causes acting from distant centres of force. We are in ignorance as to the subterranean operations of electrical and calorific agents still constantly going on; and to these theoretical difficulties must be added the unconquerable impediments to accurate and varied observation of the facts on which inferences are to be founded. Minute analogies of the relation of veins to the adjacent rocks would therefore at present be very unsatisfactory and hypothetical, and we must be content with the results which may be gathered from wide and general comparisons of phenomena on the grand scale. We shall confine the inquiry to metalliferous veins.

1. *Relation to the different kinds of Rocks.*

Considered as to their chemical nature, rocks may be classed as calcareous, argillaceous, silicious, and mixed; as to their mineralogical characters, as uniform, or varied, granular, compact, or crystallized; as to their origin, aqueous, igneous, or pyrohydrogenous. Metalliferous veins occur more or less frequently in every one of these classes of rocks. In limestone, in argillaceous slate and shale, in quartz and sandstone rocks, and in rocks of mingled ingredients; in uniform slates, and fragmentary millstone grit, in granular sandstone, compact limestone, and crystallized limestone and granite; in sedimentary grits and shales, in pyrogenous porphyries, basalts, and metamorphic conglomerates. The existence of mineral veins in a rock is therefore wholly independent of the particular chemical and mineralogical nature and proximate origin of that rock; nor, when due allowance is made for the relative prevalence of the different kinds of rocks, does there appear any reason to admit that any preference or more frequent occurrence of metalliferous veins in rocks of particular kinds can be traced, *except in particular districts.*

Veins of certain metals.

There yet remains the inquiry whether certain metals are specially associated with or related to particular sorts of rocks. In order to answer this question satisfactorily, we must not content ourselves with instances such as tin veins and mercury veins, which occur in so few localities as to be rather dependent on their geographical position than on their geological repositories, but must cite veins of lead and copper, and disseminated ores of iron and manganese. Hardly any substance is more abundant in the mineral kingdom than iron pyrites: it occurs both in veins and disseminated crystals or concretions; and, in one or other of these states, it is associated with almost every known rock. It occurs disseminated in limestone of various kinds, as primary limestone, carboniferous limestone, and chalk; in clay slates, shales, and clays; in greenstone, amygdaloid, and basalt. Veins containing iron pyrites traverse rocks of as great diversity. Copper pyrites is not disseminated through so many rocks as iron pyrites, but it occurs in veins which traverse limestone, sandstone, and shale, clay slate, mica schist, granite, &c. Ores of manganese are also very generally diffused through rocks of very different kinds. The converse is true. In one and the same kind of rock occur veins of copper, lead, silver, and tin.

Affinities of metals to certain rocks.

There are some metalliferous veins which traverse different sorts of rocks, and give us an opportunity of ascertaining whether any differences in the contents of the veins correspond with the variations of the rocks. The tin veins of Cornwall sometimes pass through clay slate and granite; they produce ores in both. "A vein that has been productive of copper ore in the clay slate, passing into the granite, becomes richer, or, what is more remarkable, furnishes ores of the same metal differently mineralized. If we pursue it further into the granite, the produce of metal is frequently found to diminish. A change of ground is looked upon by miners as affording reason to expect an alteration for better or worse." Taylor, *Report on Veins.*

In Silesia.

Remarkable instances of this relation are given by Von Dechen (De la Beche, *German Trans.* 594.) The numerous veins which cross the steeply inclined strata of greywacke in the Liegen district, are metalliferous in narrow bands *parallel* to the inclined beds of greywacke. The veins of the Kupferberg, in Silesia, bear ore only in the hornblende schist, and are impoverished in mica schist. At Joachimsthal the mica schist is traversed by quartzose porphyry in veins, which, as well as the contiguous rock, hold pyrites. The rothegang of Elias consists in mica slate of loam, and holds only uranite; where it runs between mica schist, and a porphyry vein, and where it traverses the latter, its substance is a red hornstone, and it bears vitreous silver, native silver, arsenical-kobalt, bismuth glance, kupfernickel, arsenic, and bismuth; but red silver, elsewhere abundant, is entirely wanting.

In North of England

In the lead veins of the North of England, which are situated in the carboniferous limestone tract, a singular dependence is observed between the contents of the vein and the nature of the adjacent rock. The vein divides limestones, sandstones, and shales, and these are brought variously into opposition by the dislocations which accompany almost all the veins. The vein is sometimes productive of lead ore under every case of opposition on rocks. Where limestone, or schist, or solid sandstone forms the walls, its productiveness is at the maximum, but generally it is contracted in breadth and impoverished in its metallic contents, wherever it is included between walls of shale, and even where only one side is occupied by shale, the same effect is frequently observed. It would appear that the impoverishing influence of the shale is referrible to mechanical causes. In the same way as the shales in a coal-pit swell out from the undisturbed parts to fill the artificial vacuities, so we may conceive them to have done into the natural fissure; this will account for the contraction of the vein. In the process of crystallization, to which all the contents of a vein are subject, it seems conformable to analogy to suppose, that the permanent walls of limestone and gritstone would permit a more early growth of sparry and metallic crystals, than the crumbling edges of shale; a supposition, perhaps, confirmed by the occasional mixture of shale in the sparry mass of a vein, where it is "nipped," as the miners say, in beds of shale. There may be something in this due to electrical affinities, and we may perhaps apply the same supposition to the cases in Cornwall and Germany, quoted above, where the deposition of the ores is influenced by change of ground.

Quantity of lead ore from different beds of limestone.

From some or all of these causes it happens in the North of England that *certain* limestones are very much more productive than the others; in different mining districts, *different* limestones are thus favourably distinguished, but in the country of Alston Moor, Teesdale, and Swaldale, the uppermost thick limestone is by far the most rich in lead. To prove this, and at the same time to record a valuable fact, we may copy from Mr. J. Taylor's Report on Mineral Veins (*Reports of the British Association*, vol. ii.) the following statement of the quantities of lead ore actually extracted from the several sites of bearing beds in Alston Moor in the year 1822, according to the account of Mr. Dickenson; we have added the thickness of the several beds.

	Thickness in yards.		
Limestone beds :—			
Great limestone	21	20.827	Bings of 8 cwt. each.
Little limestone	2	287	
Four fathom limestone	8	91	
Scar limestone	10	90	
Fine bottom limestone	8	393	
			21.688
Gritstone beds :—			
High slate sill	8	107	
Low slate sill	7	289	
Firestone	11	262	
Pattinson's sill	4	259	
High coal sill	4	327	
Low coal sill	3	154	
Tuft	3	306	
Quarry hazel	10	44	
Nattrass gill hazel	6	21	
Six fathom hazel	12	576	
Slaty hazel	4	18	
Hazel under scar limestone	4	2	
			2.365
Whole produce of the mines of the manor, 1822.			21.053 bings.

Upon the whole there is no sufficient evidence to show that the local *production* of metallic substances is in any special manner dependent upon the chemical or mineralogical composition, or the circumstances of the forma tion of the adjacent rocks, though in some particular, and, indeed, many instances, we observe the *aggregation* of the substances in the vein to have been decidedly influenced by some peculiar conditions of the including rocks.

Walls of a Vein.

Alteration of substance.

Slickenside.

The walls or cheeks which form the more or less definite boundaries of the vein present several facts worthy of notice. In some instances they are highly indurated, as if in contact with trap rocks, (North of England,) very often fissured, so as to break parallel to the vein, in others it seems as if certain sorts of rock (as clay slate, both in Cornwall and Germany) were greatly softened, and even converted to clay, along one or both sides of a vein. Werner mentions the decomposition of felspathic and hornblendic rocks for a fathom from the vein. We have also witnessed the fact of limestone, usually a blue or grey crinoidal rock, burnt, as the miners term it, that is converted to a brown granular crystalline rock. (Teesdale.) Another remarkable effect in the walls is the production of slickenside, so long known in the mines of Derbyshire, which are situated in limestone, and filled with fluoric and barytic shales and yield lead; in those of Cornwall, which are in killas, and with a matrix of quartz, and yield copper; in the magnesian limestone of Yorkshire, where copper or lead lines the limestone cheeks; and in the faults of the coal system of Yorkshire, where neither spar nor metallic matters occur. These and many other occurrences of rubbed surfaces along planes of fissures speak a plain language, and prove to the fullest conviction, the mechanical movement of the sides of the fissure upon one another, or upon the contained substances. The groovings of the surfaces, thus produced by rubbing, indicate, of course, the line of the movement; the circumstance that the polished faces are partially covered by lead ore, copper ore, &c., as the nature of the vein is, proves, moreover, that the movement was, in such cases, posterior to the introduction of the whole or a part of the mineral impregnation, so that the same fissure has been, in such cases, the plane of more than one convulsive movement. We may, perhaps, eventually draw from examinations of this phenomenon, in connection with and apart from mineral veins, some decisive results as to the time and other circumstances connected with the movements of the masses. How can the Geologists of Cornwall doubt the reality of those angular movements, which have left such clear evidence as the fine slickensides of some of their veins of fissures? We think with Von Dechen (*German Transl. of* De la Beche's *Manual*) that any other than the received explanation adopted above is impossible.

2. *Relation to the different Ages of Rocks.*

This relation evident.

There can be no doubt of the fact that the local occurrence of metallic veins is in a very great degree dependent on the relative antiquity of the rocks in the district. It is in the primary, transition, and carboniferous strata, and in the igneous rocks associated with them, that all the veins in Great Britain are worked. In a few instances veins of small value, producing lead and copper, pass through the magnesian limestone, but not a single example is known of a true metallic vein in the oolitic, cretaceous, or tertiary strata, The connection of metallic veins with the older rocks is not an accidental coincidence, but a constantly recurring phenomenon, and the absence of such veins from the newer strata in England cannot be resolved into any circumstances of the geographical position of these strata; for both around the metalliferous slates of Cumberland and limestones of Derbyshire, the new red sandstone formation is extensively spread in contact, and yet not one lead or copper vein occurs in it. Any one who should confine his attention to the British Isles might infer that the causes of the production of mineral veins had been almost wholly inactive ever since the carboniferous epoch; and as a general expression, this may apply to the Continent of Europe, though both in the Pyrenees, and around the central granitic tract of France, metalliferous veins, apparently originating in these rocks, traverse strata of the oolitic and cretaceous systems.

The same relation obtains in rock dykes.

It must here be remarked, that both in Great Britain and throughout Europe rock veins and basaltic dykes are in the same manner abundant in the primary and rare in the secondary and tertiary strata. This is one of many general analogies tending to substantiate the opinion previously advanced upon more specific points of agreement, that rock veins and dykes, and metalliferous veins, form two parallel series of igneous products developed during the same geological periods, by the same general causes, acting under different circumstances upon different materials. From all our previous investigations, we have been led to the conclusion, that in the earlier geological periods, the chemical effects of heat and mechanical effects of heat were more conspicuously exerted; and if to this we join the consideration that all the disruptions by which igneous rocks were put in contact with secondary and tertiary strata, must have been experienced by the older strata, from beneath which the expansive force originated, we shall be able to perceive why the primary are so universally and the secondary and tertiary strata so partially enriched with mineral treasures and diversified by rock dykes.

Very modern veins.

As an example of veins of more recent date, we may quote Von Dechen's notice of the veins of Joachimsthal. In this case the dykes of basalt and wacke which divide the mica slate are themselves cut through by the mineral veins. These dykes are variously connected with great overlying masses of basalt which break into the brown coal formation. It is therefore evident that the silver, arsenic, and kobalt ores have been thrown into the veins at a later epoch than that of the brown coal tertiary deposit at the foot of the Bohemian Erzgebirge.

Werner appears to have been strongly impressed with the belief, conformable to his general theory, that vein formations might be classed as to their ages by mere examination of their component substances. When veins, even in distant Countries, contain the *same* ores and vein stones, and when these are arranged in the same determinate order, he concludes that they belong to one and the same general formation. Illogical and hazardous generalizations are frequent among practical men, and are too often introduced among the valuable facts recorded as a basis for Werner's Theory of Veins. A prudent reasoner would scarcely venture to trust an inference for *time* upon data which indicate only definite *chemical action*, even in a limited district, and it must be with some distrust that we can admit Werner's eight principal vein formations in the mining field of Freyberg; because he does not state *expressly* that his inferences concerning their relative antiquity were based on observations of their intersections.

Werner's eight systems.

The following abstract of the account of these eight systems of veins will show the kind of description which should always be given of mineral veins.

The first and oldest produces abundance of argentiferous lead glance. It consists of coarse granular lead glance with from one and a half to two and a half ounces of silver per quintal; common arsenical pyrites; black blende in large grains; common iron and hepatic pyrites; sometimes a little copper pyrites, and a little sparry ironstone. The veinstones are chiefly quartz; sometimes a little brown spar; rarely a little calc spar. These substances occur most generally in veins ranging from *North to South.*

The second yields lead very rich in silver. It contains lead glance large and small granular; black blende in small grains; iron and hepatic pyrites, and a little arsenical pyrites. In addition, dark red silver ore, brittle silver ore, white silver glance, plumose antimony ore. The veinstones chiefly quartz, with much brown spar and often calc spar. The veins range *South and South-West.*

The third yields lead glance with one ounce of silver per quintal, much iron pyrites, a little black blende, and red iron ochre. Veinstones quartz, sometimes with chlorite mixed and surrounded with clay. Veins range *North and South.*

The fourth yields lead glance with one-fourth to three-fourths of an ounce of silver per quintal, radiated pyrites, and sometimes brown blende. Veinstones heavy spar, fluor spar, a little quartz, and rarely calc spar. Veins range *East and West.* (To this system Werner boldly refers the veins of Derbyshire, the Harz, and also those of Gisloff in Scania!)

The fifth consist of native silver, silver glance, and glance cobalt, sometimes with grey copper ore, lead glance rich in silver, fine grained brown blende, and sparry ironstone. Veinstones, heavy spar in a state of disintegration, and fluor spar. It always occurs in the *intersections* of the first and fourth systems. (North and South, and East and West.) It sometimes is found even in the middle of the Westerly veins.

The sixth contains native arsenic and light red silver ore; with a little orpiment, copper nickel, glance cobalt, native silver, lead glance, iron pyrites, and sparry ironstone. The veinstones are heavy spar, green fluor spar, calc spar, and a little brown spar. Occurs in the intersections of the fourth and fifth systems, or in the middle of veins.

The seventh is of red ironstone, with a little iron glance, quartz, and heavy spar. Occurs in the *upper parts* of veins.

The eighth and newest is of copper pyrites, mountain green, malachite, and red and brown iron ochre, with a little quartz and fluor spar.

3. *Relation to the Local Centres of Igneous Action.*

Our investigations lead directly to the inquiry, how far the geographical occurrence of metalliferous veins is connected, as that of rock dykes is known to be, with the eruption of igneous rocks and the movements of fluid masses within the Globe?

Satisfactory evidence on this subject can be obtained in two ways: 1. By comparing metalliferous and non-metalliferous districts of old strata in their geographical relation to igneous rocks and convulsions. 2. By comparing the relation to igneous agency of the locally metalliferous newer strata.

In older rocks.

The older rocks are not by any means universally stored with metalliferous veins any more than with rock dykes. Very large tracts in the slate rocks of Devonshire are nearly devoid of metals, but near the granitic masses of Cornwall they are abundantly supplied with veins. In the vast districts of Wales the slate rocks yield copper and lead chiefly along the Western borders of the Principality, where the local centres and axes of elevation are situated. Amid the Cumbrian Lakes, lead and copper veins adjoin the granitic, hypersthenic, and syenitic axis of Carrock, Skiddaw, High Pike, &c. They occur near the porphyries and traps of Helvellyn and Old Man, but the greater portion of the slates, far removed from the foci of disturbance, are devoid of mineral treasures.

In Scotland, metallic veins adjoin the granitic nucleus of Strontian.

The mining tracts of the Harz, the Erzgebirge, Hungary, Brittany, and other localities are convulsed by disruption and diversified by the intrusion of granitic and porphyritic rocks; the Ardennes mountains, which yield few veins, develope hardly any igneous rocks.

The carboniferous limestone tracts of Mendip, Derbyshire, and Flintshire, of Wharfdale, Swaledale, and Aldstone Moor, have been shaken to pieces by many convulsions, and they are very rich in lead, zinc, and calamine; but the greater part of the Yorkshire and Northumberland limestones, affected by only one or a few general elevations, are poor in metal.

In newer rocks.

The newer rocks are metalliferous only in the vicinity of the foci of their disturbance, as round the central granite of France, near the igneous masses of the Pyrenees and the Alps; in all which places, the metallic ores are so related to the igneous rocks that they occur only in a narrow zone at the junction of the igneous and the altered stratified rocks. (Observations of Dufrenoy, Von Buch, &c.)

Conclusions on this subject.

As both these methods of comparison lead to one result we may venture to adopt it; and the more readily because, in preceding sections, we have found the geographical situation of mines to be related to the elevation of the ground, and the metalliferous strata often identical with those in which rock veins abound. Nevertheless we must not shut our eyes to some decided differences between the situations of dykes and veins. For instance, the Island of Arran is traversed by hundreds of dykes of basalt, porphyry, and pitchstone, but metallic veins are almost unknown there; Aldstone Moor is dissected like a map by veins of lead ore, but very few whin dykes occur there; on the contrary, in Northumberland and Durham whin dykes abound in the coal tracts where lead is hardly known. It is, besides, too remarkable a thing to be overlooked, that South of the Yorkshire Swale hardly a whin dyke or porphyry dyke is known through the metalliferous tracts of Derbyshire, Somersetshire, and Flintshire. This contrast is the more remarkable in the country about the sources of the Tyne and Tees, because there basalt has been erupted in vast quantity, and at its Eastern termination appears related to several dykes of great extent. This mass of basalt is traversed by the veins in the same manner as the limestone is, and we may, perhaps, hazard the speculation that under this tract of country lay at one time melted basalt, and at a subsequent time the metallic and mineral combinations which fill the veins. Will it be thought too great a stretch of fancy to attribute this change of the igneous materials erupted in the same tract of country to movements in the internal nucleus of the Globe not isochronous with the rotatory velocity of the solid superficial crust?

Electricity of Veins.

Mr. Fox's experiments.

The direction of electrical currents at small depths below the surface of the Earth, is a subject on which theory is at present silent, and which has only recently been proposed for observation. The observations of Mr. Fox in the mines of Cornwall and Devon and North Wales, are still the most important of the kind. Mr. Henwood is engaged in further inquiries. As far as appears at present, the interest attached to the solution of this question belongs more particularly to Electrical Science, and, perhaps, both chemical and thermal disturbances of equilibrium may be concerned in the effect. These currents may be due to local causes. Mr. Taylor very properly observes, (*Reports of the British Association*, vol. ii. p. 18.) that by the very act by which we gain access to a vein we lay it open to atmospheric action, and consequently to decomposition. Chemical agency commences, and with it, very naturally, galvanic influences are excited. Veins containing ores little subject to decomposition have, he apprehends, been found to give little or no indication of this nature.

Mr. Fox appears to think that the direction and intensity of the currents which pass along the veins may be so related to the position and quantity of metallic matter, as to give reason to hope for some direct useful application of the results to the Art of Mining. But the novelty of Mr. Fox's experiments, and the connection of the currents with mineral veins, led some Geologists to adopt the very hasty conclusion, that the production of the veins was mainly owing to such currents. It is very probable that electrical currents have really been concerned in the distribution of metallic ores both in veins and rocks, for when is this agency absent from any great chemical phenomena? But to conclude, without any intermediate steps, because mineral veins are channels for electricity, that they have been produced by electricity, is the same thing as to ascribe to electrical currents the construction of the galvanic battery.

CHAPTER IV.

GENERAL INVESTIGATIONS AND INFERENCES.

SECTION 1.

On the Consolidation and Alteration of Stratified Rocks.

In a preceding section we have seen the effects produced by the Plutonic rocks upon the strata which they penetrate; effects which suggest to our minds so vivid an impression of the action of heat, that even in the absence of all other arguments from facts, we could not refuse to allow that those rocks had been local centres of heat. The independent evidence arising from the composition of the rocks satisfactorily confirms this inference, and permits us to apply it in circumstances when the actual proximity of igneous rocks cannot be ascertained. These effects seem to be reducible to several cases, depending on the degree of heat communicated, and the substances operated on.

Effects of Plutonic on stratified rocks.

1. The *consolidation* of stratified rocks is exemplified in the induration and contraction of shale, and in the developement of new faces or joints in it, which sometimes meet one another rhomboidally, and sometimes follow the columnar relations of the adjoining basalt.

2. The *partial fusion* of some part of the substance of a rock, so as to conglutinate its grains, and solidify and harden the whole mass. Thus sandstone is converted to a granular quartz rock.

3. The complete fusion or vitrification of the rock; thus converting shale into Lydian stone and sandstone into a kind of jasper.

4. The complete fusion and consequent rearrangement of the particles into granular or crystalline forms, as in the instance of common chalk in Ireland, common limestone in Yorkshire, the Isle of Sky, and Carrara.

5. The generation of minerals not before existing in a distinct state in the substances affected. The production of pyrites, asbestus, anthracite, plumbago, garnet, &c. along the contact of igneous and aqueous rocks, is a very characteristic and general effect which appears to result from the actual transfer of the metallic and other matter through the solid substance of the rock, in virtue of electric attractions which may be considered as imparted by the heat.

If Von Buch's notion of the impregnation of rocks with magnesia in the vicinity of augitic trap rocks should eventually be substantiated, it must be considered as a remarkable example of this electric transfer.

6. The sublimation of some portion of the neighbouring substances. Thus the charring of coal, the desulphuration and the debitumenization of shale, are very directly connected with the heating power of the igneous rock, but it is probable that some peculiar conditions were required for such effects in the submarine depths, where most of these operations were performed.

Relation of igneous rocks to convulsions.

The almost universal coincidence of convulsive dislocation of the strata with eruptions of plutonic rocks, seems enough to prove their common dependence upon one pervading cause of internal movement. In the same manner as the modern earthquake precedes the eruption of lava, so the ancient convulsion preceded the injection of plutonic rocks. Also precisely as in the present day the earthquake shakes Countries far removed from volcanic centres, so in more ancient periods many tracts were convulsed but not filled, at least near the surface, with melted rocks. As far as at first appears, the common dependence of the two orders of effects upon one cause, is merely to the amount that the mechanical transference of melted rocks has been effected by the same internal pressure which dislocated the strata; whatever occasioned the pressure, and whatever was the cause of the fluidity of the rocks.

Various mechanical modes may be conceived, by which such pressure may have been occasioned, and various conditions assumed for the production of melted rocks, and these may be wholly distinct from one another; but the *exhibition* of these rocks along the lines of convulsion can only be ascribed to the same mechanical cause which produced the convulsion.

The chemical theory of volcanos, advocated in the preceding pages, assigns a single cause for the chemical phenomena, and for the disturbance of the external crust of the Earth; and the same simplicity is sought for in one modification of the theory of an internal heated nucleus; but it may possibly be more correct to assign separate causes for the production of these effects. Judging merely from their relative frequency and geographical extent, we might be led to assign much more extensive agencies to the production of convulsions than to the elevation of igneous rocks. The whole area of the dry land has been subject not only to general elevation but to partial convulsions, several times repeated under the same spots; but igneous rocks are less universally, though certainly very extensively diffused. This distinction, however, loses much of its force when we consider, first, that plutonic rocks become constantly more and more abundant in comparison to the number of convulsions as we descend towards the base of all the strata; secondly, that though the effects of convulsion might pass through all the strata to the surface, and thus relieve the inequality of pressure, the melted matter from below could seldom penetrate the narrow and confused and cold passages left among the fractured strata, to any great elevation; thirdly, that rocks of igneous origin do really underlie the whole series of strata.

General basis of argument.

Upon the whole we may safely admit, that igneous rocks have been in a state of fusion beneath the strata, either simultaneously or successively, in all or nearly all parts of the Globe, and that the elevation of those has been always accompanied by convulsions. Instructed by the discovery of the effects of these rocks upon adjoining substances, we may now proceed to inquire into certain phenomena, of much more extensive occurrence, but of nearly a similar character, and which appear due to the pervading action of heat upon stratified rocks since their deposition.

Ratio of the consolidation of strata.

On reviewing the series of strata in relation to the degree of their consolidation, it is impossible not to perceive that this increases continually with the age of the rock; so that, taken as a group, the primary systems of gneiss and clay slate, with all their modifications, are far more consolidated than the other strata, while the tertiary strata are the least indurated of all. The same result is obtained by more minute comparisons of analogous rocks, the slates, shales, and limestones of the primary series, with the shales, and clays, and limestones, and marls of the secondary and tertiary strata. A plausible cause for this seems to offer itself in the greater pressure to which, it may be imagined, the lower strata have been subjected; but this is not sufficient to account for the whole effect of consolidation, and is directly negatived by the numerous joints and fissures, which indicate lateral rather than vertical contraction of the strata. The lowest strata are, besides, not merely in a high state of consolidation; some of them, as primary limestone, display in a most decided manner that crystalline structure which results from heat; others, as clay slate, are fissured in such a way as is known to have been locally occasioned by the heat communicated from igneous rocks; others, as quartz rock, show clear proof of having undergone, if not actual fusion, at least such an agglutination of the grains as can be produced by art in a furnace. The conclusion from all this is of great importance; for as these rocks are of almost universal occurrence below all the other strata, and their characters are not referable to the local proximity of igneous rocks, we are assured, taking into account the subjacent granitic rocks, of the almost universally pervading influence of subterranean heat.

Alterations of primary strata.

It is impossible at present to point out exactly the amount of changes which have been produced on the primary strata by the general and continued communication of heat from below; because, with respect to some of them, it is difficult to feel very confident of the precise state in which they were deposited by water. With respect to gneiss, for example, which is in some cases almost identical with granite, in other cases approximates to sandstone, it is hard to say how much of its granitoid character is due to subsequent metamorphism; because we have no certain means of knowing the degree of movement to which its ingredients had been exposed in water. Yet when we consider the bedded and laminated character of this rock, and observe that its constitutent minerals are mostly in a fragmentary state, and even when united into a dense rock, are not crystallized with regular external forms, we seem to understand that the rock has been solidified by a species of imperfect fusion at the edges of the constituent substances, which, carried to extreme, would have reconverted the whole to granite.

Similar remarks apply to mica schist, which, on the one hand, varies to gneiss, and on the other to clay slate; and it is observable that the fusible mineral garnet, which is known to have been generated at moderate heats in contact with trap, is very generally intermixed with the laminæ of gneiss and mica slate. (p. 562.)

Of clay slate.

Among clay slates of every degree of fineness of grain, the action of heat is chiefly evinced by the extreme condensation of the argillaceous substance; by the regularity of the system of fissures; by the interspersion of crystallized pyrites, hornblende, &c.; by the frequency of segregated quartz veins. Perhaps these latter occurrences may be due to local causes; but the systematic fissures and cleavage of slate is a general fact, which is most striking in the deeper parts of the deposit, and gradually vanishes upward. So long as the basis of the rock is very fine grained, the cleavage structure will pervade it, and even cross laminæ of very course matter; but when the basis is altogether coarse, as in greywacke slate, the cleavage vanishes, and is only indicated by numerous fissures, dividing the rock into rhomboidal masses. In a given tract of country the planes of cleavage have one prevalent direction, and the system of fissures appears also definable in direction. The general horizontal direction of the cleavage planes in a part of the Cumbrian mountains is West North-West, which is exactly that of the great Craven fault. (*Geol. Trans.* New Series, vol. iii.)

It is usual and probably correct to consider the systematic fissures and cleavage of slate as a kind of crystalline structure on the largest scale; the angles of intersection seem, however, to be assignable only for very small distances, and they vary in different strata of slate. Something like polarity must perhaps be supposed to account for the constancy of the direction of cleavage.

It does not appear that the heat imparted to the primary strata has been always sufficient to destroy the organization of shells or even plants, for shells occur in the slates of Tintagel and in Snowdon, and lie between gneiss beds in the Fichtelgebirge and Erzgebirge, and are noticed by Von Buch in the dolomite near Lugano. A long continued and pervading rather than a very high heat seems best to account for the phenomena. In the neighbourhood of igneous rocks, indeed, the local changes are of rather a different description.

If we rise to the contemplation of the carboniferous system we shall be able to trace in the generally high state of induration of the sandstones, shales, and limestones, and in the frequency, systematic direction, and continuity of the joints, clear evidence of the action of heat. But yet we perceive that these effects of heat are not nearly to the same degree as those in the primary strata. A simple proof of this is afforded by the limestone of Teesdale which is a hard rock, but which, where it touches the basalt of that country, has been subjected to nearly the same change as that observed in primary limestone: it has become crystalline. The shales are also altered. The upper portions of the slate system in Shropshire and Radnorshire, where that system is immensely thick, show the same changes.

Dec ng effects of heat in newer strata.

The effects of general heat continually decrease among the superior strata of the saliferous, oolitic, and cretaceous systems, and seem almost wholly lost in the tertiary strata. It is chiefly to this graduated effect of heat that we may ascribe the distinctness of the rocks in different parts of the series. Thus to take the calcareous rocks, we have a gradually changing series proportioned to their antiquity, from crystalline primary limestone, through highly condensed carboniferous limestone, to compact lias, concretionary oolite, marly chalk, and lacustrine marls; among sedimentary deposits there is a series from gneiss through the hard sandstones associated with the carboniferous limestone to the sands of the oolites, chalk, and tertiaries; and another from cleavable slate, through jointed greywacke slate, hard coal shale, compact red marl, and clay of the oolite, chalk, and tertiaries. There is properly no sand, clay, or marl among the older strata; indurated shale, hard gritstone, and solid limestone are of rare occurrence among the younger.

It does not appear that the occurrence of ironstone, pyrites, gypsum, &c. in detached masses among the stratified rocks is to be considered as in any direct or exclusive manner due to the influence of heat, but rather to the ordinary forces of molecular electric attraction operating during or after the deposition of the mingled mass of matter. The spar veins in septaria have undoubtedly been filled since the concretion of the clay balls, and for the transfer of the calcareous or silicious matter we must appeal to the same processes which have filled the cavities of shells and many cracks in limestone rocks with the same materials. No doubt in these effects an elevation of temperature might modify and perhaps accelerate the results, but it would be ridiculous, at present, to adopt Dr. Hutton's notions on some of these subjects.

Effects of heat on the deposition of strata.

The preceding examples show clearly the effect produced on strata by the action of heat since their deposition; there can be no doubt that the same powerful agency must, especially in the earlier eras of Geology, have greatly influenced the manner and circumstances of their deposition. On this subject, however, we have not at present much to record, and that little is wholly confined to the primary series of strata. There is one leading fact often connected with the stratification of gneiss, mica schist, &c. and not seldom repeated in chlorite schist and clay slate, which seems wholly unexplained by the direct action of heat upon these strata. The *contortions* of the laminæ of these rocks are very remarkable, and seem evidently coeval with their first formation, though in some instances Dr. Macculloch thinks they are most numerous where quartz veins penetrate the rock. These contortions may, perhaps, be understood by comparing them with some analogous cases in laminated sandstone, where the undulations and confusion of the laminæ indicate agitation in the water. If we allow that the water in which gneiss and mica schist were formed, was heated to a great degree by contact with or proximity to the sources of subterranean heat, the agitations of the ebullient liquid might, possibly, give to the strata then forming under it the very peculiar character of minute and irregular undulations which so often belong to these ancient rocks.

Deposition of limestone.

Another thing apparently characteristic of the mode of deposition of the primary strata is the isolated condition of the limestones which interlaminate the schistose rocks. How different in this respect are the detached often lenticular primary limestones of Scotland, and even the transition limestone of Devonshire and Wales, from the regularly continuous calcareous beds of lias, oolite, and chalk! Is it not very probable, that some local efflux of gases or the influence of local centres of heating agency, have sometimes performed the same effects as coral animals, and determined to particular points the extremely limited decomposition of the ocean water which undoubtedly was the source of the limestone deposit?

Section 2.

On Disturbances of the Strata.

The introductory observations in p. 540 to 543 may serve as a foundation for the following inquiries into the effects and causes of subterranean convulsion; and the remarks in p. 571, 597, 619, 634, 657, 688 may be read in connection with the preceding section of chap. iv. and the whole of chap. iii. This great subject may be carefully considered in four divisions.

1. The geological periods of convulsion.
2. The direction of convulsive movements.
3. The effects of convulsions in altering the relations of land and water.
4. Effects on the deposition of strata and on organic life.

Geological Periods of Convulsion.

Proofs of convulsion.

In order that our statement of results on this important subject may be as much as possible free from objection, it will be convenient to begin by fixing what phenomena are to be taken as proof of the occurrence of convulsions, and what method is to be followed in assigning their place in the scale of geological epochs. When strata, originally level, or nearly so, have been raised to high angles of inclination; when beds, originally continuous, are found to be broken asunder, and their separated portions placed in new relations of position, one portion being raised or depressed, or both deranged; when layers, originally plane, are found to be bent into extraordinary curvatures; in all these cases the conclusion is immediate, that convulsions have happened in the very points where such phenomena occur. The only question which can arise, supposing the actual position of the rocks well ascertained, respects the certainty of our postulate of their *former* position. Persons who have read old books, but have not studied natural phenomena in this point of view, may be apt to suppose that, under particular circumstances, strata may be formed at high angles of original inclination. Those who have looked more narrowly into the matter, and have been instructed by Mr. Yates's observations on the positions assumed by earthy materials falling in air and in water, may be led to extend the judiciously limited inferences of this author to cases where they will not apply. For very limited areas, and in extremely troubled waters, the mountain torrents, or the surf of the ocean, tumultuous deposits of sand and pebbles happen, in which the laminæ may be inclined at considerable angles, and cover one another confusedly. On this account it seems not unnecessary to reexamine the basis of our argument, and see whether it will bear the weighty superstructure we design to lay upon it.

Examination of the basis of the argument.

1. General experience assures us of the general fact, that it is a characteristic effect of agitated water to deposit what sediment falls slowly from it in the form of strata whose upper surfaces continually tend to become horizontal. This is seen in inundations from a river, in shallow and ruffled lakes, and within the low-water margin of the sea. The form of the bottom influences the horizontality of the upper surfaces of the deposits in such a way, that where the bottom is like a pit, the stratified masses above are hollow on the faces; but these effects of the original inequality are rapidly obliterated by successive coats of sediment, all becoming more and more nearly horizontal.

2. In perfectly tranquil water, through which any fine sediment is equally diffused, the depth to which this will cover any part of the bed depends on the depth of the supernatant water, and on the *angle of rest in water* of that kind of sediment. The *angle* of rest *in air* for earthy substances is about 45°.

3. If a river bring sediment into agitated water, this will deposit it in strata tending to become horizontal, but with a constant dependence upon the point where the river enters, such that, the quantity of sediment being there always accumulating, a general conical slope therefrom in all directions will modify the horizontality of the strata.

4. If a river bring sediment into calm water, or into water suddenly deepening, so that all its lower parts may be considered as calm, the conical slopes from the point where the river enters will be much more abrupt than in the former case, in a certain proportion to the calmness and depth of the water. This Mr. Yates finds to be the case in the deep lakes which receive the abundant sediment of the boisterous torrents of the Alps; and, in consequence, we are furnished with a key which will ultimately open many curious results in the arrangement of sedimentary deposits. (See p. 707.)

On considering these cases with reference to stratified rocks, it is evident that instances coming within the class of conical deposits radiating round a point can only be of very limited occurrence, not likely to affect a general argument, and are, in fact, almost unknown. The estuary deposit of the Weald of Sussex shows no such structure; it cannot be traced in the Yorkshire estuary coal field; nor is there any mention of it in any lacustrine deposit which has been desiccated and exposed to our observation. It is very doubtful whether it can be recognised in any marine formation, and certainly it does not clearly apply to any class of marine deposits now in progress: at the same time we must admit that, in all cases, the action of the sea growing less and less sensible far from shore where the water deepens, the sediment brought by rivers and floods must be formed in attenuated masses, thickest towards the shores. This effect will be evident in exact proportion to the *falling velocity* of the particles in water, so that pebble beaches may lie in steeper slopes, and cover shorter breadths than sands, while fine clays will spread further into deeper water. (See p 709.) But all these slopes *in water* are very gradual, so that even against the rocky Eastern coasts of England, the deep waters have been filled up by sediments, which now assume a gently declining surface under the water, and a moderate slope above it.

Direct proofs of local convulsions.

For all the purposes of our present course of argument we shall therefore assume the law of original horizontality, or very moderate declination of the planes of *widely extended strata*, as amply supported by every needful proof from careful and scrupulous observation. Hence from adequate observations of the position of strata we can tell whether they have been altered in position or not by convulsions operating in those situations precisely.

Indications of convulsions.

Another class of appearances indirectly marks the effect of convulsion, either on the spot or at some distant point. When we find traces of a sudden and complete change in the whole course of the aqueous deposits, so that the quiet deposition of argillaceous or calcareous strata is interrupted and preceded by a tumultuous aggregation of pebbles, we know that there has been some access of agitation to the water. This may, according to circumstances, have happened from a periodical or accidental change in the drainage of the neighbouring land, or from some extensive change of the relations of land and sea. The latter cause may be reasonably adopted, provided that we find these indications of agitation very extensive, and provided that in some instances there be proof of the formation of local conglomerates following upon local convulsions. The latter requirement is found to be satisfied in many instances, and of the former it is easy to judge. One more indication of some distant convulsion affecting the relations of land and sea seems to be afforded from the rare case of the occurrence of one bed of marine shells among a vast abundance of fresh-water estuary deposits, (see p. 591.) without any local unconformity of stratification.

Such are the phenomena to be taken as proofs of convulsion: the most important are those which distinctly establish the precise localities of the disturbance. Let us now examine into the mode of argument by which the geological epochs of these disturbances are to be established.

How to determine the epochs of convulsion.

In all investigations concerning the period when an event happened, we may consider the result completely obtained, when the limits of maximum and minimum antiquity are known as precisely as the data allow. In geological inquiries, the answer is always expressed in terms of the scale of relative antiquity of the stratified rocks, and a convulsion is fixed in geological time, when it can be shown to have happened after the deposition of one stratum, and before the deposition of another. If the strata which thus limit the period of the convulsion be consecutive terms of the series of deposits, the most precise attainable result is obtained; but if these limiting strata be not consecutive, the age of the dislocation is known only within a given range. An example of accurate determination of the geological era of a convulsion is afforded in the North of England, where the newest of the coal strata are found to be dislocated under the oldest red sandstones of the saliferous system. Instances of less precise determinations are common enough: for example, in the Mendip hills the dislocated mountain limestone is covered by undisturbed oolite, and, as far as this observation goes, the convulsion may have happened during any part of the long period occupied in producing the coal, red marl, and lias strata. In this case, however, by tracing the line of the dislocation to other localities, other strata are found to be so related to the limestone, as to fix the geological date of its disturbance within narrower limits.

If the dislocated strata be not actually seen covered by others which are undisturbed, another set of data must be employed. It may happen that around the disturbed rocks some newer stratum spreads in such a manner as to give sufficient reason to conclude that it was deposited since the period of the convulsion. This is, in most parts, all that can be observed with respect to the red marl around Charnwood forest, and it would be satisfactory evidence that the slaty rocks of that district were upraised before the period of the new red sandstone; and, in fact, we have found instances where the red marl does really cover with level beds the broken edges of slate.

If no horizontal or undisturbed strata be visible in any part of the dislocated tract, either in superposition or in juxtaposition, the limit of least antiquity vanishes, and we are in danger of imagining too modern a date for the convulsion; if the newer members of the dislocated group of strata be concealed, there is danger of ascribing too high an antiquity to the convulsion. It will be prudent to exclude all such cases from the argument: the others seem to be unobjectionable.

Question as to the duration of the convulsions.

There is yet another point of view of much importance to the following investigations. What we have termed the limit of greatest antiquity marks clearly the completion of the convulsion; but the progress of geological inferences has brought us to the point of requiring information whether the disturbances were very rapidly effected by one or a few sudden and violent efforts, or operated slowly by small and graduated movements. According to the former view, the whole amount of the dislocation was effected in so short a time that this may be regarded as nothing compared to the long periods occupied in the deposition of the strata; according to the latter, the disturbing agency might be at work during the whole, or some long part of the period of the formation of the dislocated strata, but ceased when their formation was complete. This is not a mere subtilty or needless refinement, it is very important to know which is the true doctrine: we believe it can be ascertained, for all instances where the facts can be clearly known; and though it would be premature to make any exclusive assertion, the general process of Nature may be satisfactorily inferred.

Faults.

Proceeding from the clearest indications on this subject towards those which are less easily interpreted, we may remark in the first place that those dislocations commonly known by the name of "faults" in the strata, (p. 541.) which break the continuity of the beds along a certain plane or fissure, and elevate or depress one side, plainly declare themselves to be the result of single convulsive movements. To be satisfied of this, it is quite enough to contemplate a diagram of the effects, pl. i. fig. 5, 7; but actual inspection of the phenomena will leave no room for doubt that the whole mass of dislocated strata was put into its present relations, not by a repetition of small and gradual movements, but by sudden and violent agency. A repetition of small movements through the whole vast thickness of strata could not fail to break down those clearly defined walls of the fissure which so generally exist, especially among the harder rocks, and leave the fissure filled up with a confused aggregation of all the substances on its sides, instead of a clear space for the subsequent admission of sparry and metallic matter, or regular traces of the movement of these faces on each other.

The extent of dislocation to which the name of fault accurately applies is extremely various, the difference of level thus occasioned being sometimes a few inches, in many 100 feet, in others as much as 200 yards. This makes no difference in the argument, but it serves to mark out in very clear characters the degree of force exerted in each case. It is remarkable that those dislocations which make the greatest difference of level, range through the greatest lengths of country; so that the ninety-fathom dyke, so named from the observed extent of its dislocation, ranges from the Eastern Sea across the whole breadth of Northumberland, and certain dislocations in Yorkshire have ranges of ten, twenty, and thirty miles in one straight line.

Great dislocations.

As far as we know, the greater portion of the convulsive movements, whose production we are now investigating, were accomplished by means of "faults." There are some very extensive dislocations which usually receive, and may perhaps deserve the same epithet, but which, for the purposes of our present argument, wear a somewhat different aspect. One of the most magnificent examples of dislocation in Europe is that grand break nearly along the line of the Western border of Durham and Yorkshire, from near Brampton by Brough and Kirkby Stephen to near Kirkby Lonsdale, the effect of which is to throw down to the West, relatively, the strata of the carboniferous system more than 1000 yards through a length of 70 miles. An axis of slate rocks rises along the line of fracture, which is also partially marked by dykes of greenstone. On the West the beds dip at high angles to the West; on the East they decline gently to the East. No proper plane of fault is traceable in this case of enormous disruption, owing to the circumstances of the country, and we must have recourse to other considerations to arrive at satisfactory inferences concerning the time employed in producing it.

In the first place we may remark, that this line of disturbance is cut off to the North by the ninety-fathom dyke, and to the South by the Craven fault; and there is every probability that it is actually continued along the lines of these faults to a direction right angled, or nearly so, to its own course. If this be so, and the whole is one complex dislocation, we may surely conclude that the middle portion, even if not of the same age as the extremes, was produced in the same manner.

Relation of faults to axes of convulsion.

Again, the numerous faults of an ordinary character which cross the country in all directions between these great lines of convulsion, seem evidently related to and dependent upon them; a remark which receives corroboration from many other parallel inquiries. Amongst these faults it is possible, perhaps, to distinguish two periods of disturbance, the older one marked by a direction nearly East and West, which is that of most of the metalliferous veins, the other by a direction from North to South, which is that of several whin dykes, and some few lead veins. Perhaps these different directions may have taken their rise from the two directions of the axes of convulsion which bound the district.

The connection, however, is sufficiently clear to warrant our applying to those great axes of disturbance the limits of time by which the lesser faults are defined; that is to say, in many instances nearly coincident to the limits of uppermost coal measures and variegated new red sandstone.

Inferences. It is apparent, therefore, that the evidence which can be collected on the subject of the simple dislocation of the planes of the strata, points to violent internal movement, occupying short periods of time for the accomplishment of the phenomena. There seems to be no mark whatever of gradual or many times repeated efforts.

Some cases of disturbance, however, are of a complicated nature, and may probably be found upon further examination to require the admission of many repetitions of violent movements and pressures on the same region. Such are the extraordinary retroflexures of the calcareous strata adjoining the Alps, the retroverted dips in the coal fields of Somersetshire and Belgium, and the flanks of the Malvern hills. It is not, however, easy upon any suppositions to meet the exigencies of these difficult cases.

What are usually called anticlinal axes of elevation, must, likewise, be considered as yielding insufficient evidence concerning the length of time elapsed from the beginning to the end of the disturbance. In some cases, indeed, the dips on either side from the axis are so steep that they seem to refer themselves to single and violent movements, but where, as in the Weald of Sussex, the appearances along the axis indicate that there the disturbance has been moderate, while toward the sides it has been extreme, the breadth of the country being considerable, there seems on a first view no very good reason for coming to a decision at all, as to the prolonged or transitory nature of the convulsing agency.

There is, however, an indication worth pointing out for the future guidance of observers on this branch of the inquiry. If we imagine that during the deposition of any class of strata, an anticlinal axis is formed so that they are gradually uplifted and converted to dry land, we may be sure that all the strata would be found to grow continually thinner from either side toward the axis of elevation, at which line they would become evanescent. Very few instances can be quoted where many strata are actually seen to be continuous over the anticlinal line. The Isle of Wight, the elevation valley of Woorlhope, (*Geol. Abstracts*,) the Hampshire and Wiltshire chalk, and some remarkable cases in Swisserland, seem to be, however, sufficiently in point, and no traces of such a diminution are there observable.

General conclusion. Upon the whole, then, there is a want of proof that the disturbing forces were exerted through long periods beneath a given region, so as by many small and repeated convulsions, all operating in the same direction, to give the effect of one great dislocation. On the contrary we may believe, that the time was very limited during which several of the great dislocations and axes of disturbance assumed their respective characters. Yet, owing to the difficulty of the investigation, the question must in many instances be left wholly undecided.

The following Table shows the geological periods of many remarkable convulsions in Great Britain, and the places where some of the most considerable effects are manifested.

No.	Geological Period of the Convulsions.	Effects noted.	Localities of some of the Phenomena.
a.	During the deposition of the slate system	Production of argillaceous conglomerates	Derwent Water, Cumberland.
b.	Ditto	Porphyry and greenstone and trappean conglomerates	Grasmere in Westmoreland. Radnorshire, Herefordshire, &c.
I.	After the Cumbrian slates and before the carboniferous system	Disturbed position of primary rocks	The Grampians, Lammermuirs, Cumbrian mountains, N. Wales, Ocrynian chain, &c.
c.		Production of old red conglomerates	The Highland Border, Cumbria, &c.
1.	During the carboniferous period	Marine bed among estuary deposits	Yorkshire.
II.	Before the adjacent rocks of the saliferous system taken generally.	Numerous dislocations, fissures of dykes and veins, anticlinal axes, &c.	In all coal districts of this era, both in Europe and America. Charnwood, Crossfell fault, Craven fault.
d.	During the saliferous period?	Production of new red conglomerates	North of England, North of Germany.
III.	After, or during? the saliferous period?	Veins of lead, &c. Great or 90-fathom dyke	Yorkshire, Mendip hills, Tynemouth castle, Campsall, &c. border of Cumbrian group, (Kirkby Stephen.)
?	During the oolitic period?	Unconformity. Kelloway's rock in contact with the lower oolite group excluding the upper portion	Cave, Yorkshire, (p. 634.)
IV.	After the oolitic period	Unconformity of strata between oolitic and chalk systems	Yorkshire wolds, Dorsetshire cliffs.
2.		Estuary deposits. Pebble beds of lower green sand	In the Wealds of Kent and Sussex, Lincolnshire, Isle of Wight, &c.
	During the chalk period?	?	
e.	After the chalk period	Pebble beds, wasted surface of chalk	Hertfordshire, Vale of Thames.
V.	After the London clay	Vertical strata	Isle of Wight.
3.		Marine deposits between lacustrine beds	Ditto.
f.		The crag	Essex and Norfolk.

The Roman numerals are applied in the above list to all periods where considerable movements are traced in direct effects of dislocation and unconformity; italic numerals to those cases where a change in the nature of the water over given regions seems to result from a distant convulsion; and small letters to mark the occurrence of the most remarkable periods of conglomerates.

The next Table presents the result of a more extended survey of direct convulsive effects on the Continent and Islands of Europe.

No.	Geological Period of the Convulsions	Effects noted.	Localities of some of the Phenomena.
I. 1 and 2 E. de B.	Before the old red sandstone	Anticlinal axes and great faults of the slate system	The Hunsdrück and Taunus.
II. 3, 4, 5. E. de B.	Before the new red sandstone ... Before the rothetodteliegende ...	Immense disruptions and faults of the coal system	Calvados, South-West border of the Vosges.
	b. Before the zechstein.........	Immense dislocations and faults of coal strata	Westphalia, Belgium.
	c. Before the new red sandstone .	Immense dislocations and faults	Vosges, and Black forest.
III. 6. E. de B.	Before the lias.	Mountain ridges of zechstein, &c.....	Thuringerwald and Böhmerwald.
IV 7. E. de B.	Before the lower green sand.	Abrupt and distorted strata of oolitic system......................	Mont Pilat, Cevennes, (perhaps the Erzgebirge.)
V. 8. E. de B.	Before the uppermost chalk beds .	Abrupt elevations of green sand and lower chalk.................	Mont Viso, Devolny.
VI. 9. E. de B.	Before all the tertiary rocks.....	Elevations of chalk and green sand ..	Pyrenees, Northern Apennines, the Morea.
VII. 10. E de B	Before the nagelflue	Detached ridges	Corsica, Sardinia, Auvergne.
VIII. 11. E. de B.	Before some diluvial beds.......	Newest tertiaries uplifted..........	The range of the Western Alps, Diablerets, Mont Blanc.
IX. 12. E. de B.	During the formation of other diluvial beds...............	Some diluvial beds convulsed.....	The range of the Eastern Alps from the Valais to Austria.

Elie de Beaumont's generalizations.

It is to M. Elie de Beaumont that we owe the impulse which the study of the periods of geological disturbance has of late received, and he is the principal authority for the construction of the preceding Table. M. de Beaumont makes twelve distinct systems of convulsions which are supposed to have happened at as many distinct periods, but we do not find sufficient evidence to substantiate the division into five systems, of the first and second of our Table. The following is De Beaumont's view of these five systems including applications in Great Britain for comparison with the details of our first and second groups.

N .		Geological Period of the Convulsions.	Effects noted.	Localities of some of the Phenomena.
I.	1	Supposed to be during the deposition of the slate, certainly anterior to old red sandstone	Elevation of many mountain chains without transition limestone	Grampians, Cumbrian group, Snowdon, Cornwall, Hundsrück, and Taunus, Isle of Man, Anglesea.
	2.	Posterior to the greywacke slate, anterior to old red sandstone...	Great faults affecting transition limestone, and anthracitic slates	Devonshire, South of Ireland, Bocage in Calvados, South-West border of the Vosges. Harz ?
II.	3.	After the coal strata and certainly before rothetodteliegende.	Immense disruptions and faults of the coal	From Derbyshire to Northumberland along the Western border of Yorkshire, Malvern.
	4.	After the coal strata, certainly before the zechstein	Ditto.	Westphalia, Belgium, Mendip, South Wales.
	5.	After the coal strata, certainly before the bünter sandstein	Great disruptions.	Vosges and Black forest, from Basle to Mayence.

Direction of Convulsive Movements.

Elie de Beaumont's hypothesis.

It is impossible to make many observations concerning faults and other dislocations of the strata, without being strongly impressed by the fact that they commonly follow certain straight lines through a country, every where producing analogous mechanical movements. The length of their courses is often so considerable that one great dislocation defines the physical geography of a district. It has been long known that in mining Countries the faults take parallel directions, and sometimes two or more systems of dislocations, crossing in certain angles, were found to be of different antiquity. That dislocations were in some respects to be compared to the effects of earthquakes was also well understood, but no one before De Beaumont appears to have carried his notions of the coincidence between the lines of convulsion and the direction of the great physical features of the Globe, so far as to venture on the construction of a general system. This excellent Geologist believes that there is a constant dependence between the direction of the dislocation, and the geological epoch of its occurrence, such that all the dislocations of the same age are parallel to one and the same great circle of the sphere; and that, *in most instances*, dislocations of different ages are parallel to different great circles which intersect one another at assignable angles.

How to be examined and tested.

It will be readily understood that this general hypothesis is not to be tested by single or small dislocations. It must be examined on a great scale, by means of very exact and numerous data. It is not too much to assert, that in the present state of Geology, the facts known are not clear and numerous enough to support this hypothesis; and on the other hand there are not facts to warrant the unconditional rejection of it. It must be looked upon as a first attempt in a new field, as a generalization carried to extreme; but it is certainly founded on important data, and in several instances agrees well with observation. The principal difficulty of applying satisfactory tests to its consequences, arises from the uncertainty of the exact date of many of the most characteristic convulsions. We cannot positively tell whether the dislocations of the Grampians and Lammermuirs, which take parallel courses, were geologically synchronous or not, because the beds dislocated are not the same. Even in the case of the great faults which followed upon the carboniferous system, the limits of the geological epochs of their occurrence are too vague for the application of such a theory. In fact, De Beaumont's 3d, 4th, and 5th periods *may be* actually synchronous; so may his 1st and 2d periods be, because their *limits* are indefinite on the side of the least antiquity. Rothetodteliegende and magnesian limestone cover unconformably the coal of the North of England, and thus define the date of the convulsions; but in the South of England these are of rare occurrence, and often entirely wanting, and then the new red sandstone above the coal gives only a vague approximation to geological time.

At present these are irremovable difficulties. We can then, with strict propriety, only examine the question of the dependence of the direction of dislocations on the geological period, by comparing together, first, the directions of those dislocations which are *not* known to be of different ages; and second of those dislocations which *are* known to be of different ages.

Dislocations not known to be of different ages.

The first system of dislocations is vaguely limited as to time between some part of the primary strata and the base of the carboniferous strata. The direction of the axis of elevation of the Ross mountains, the Grampians, and Lammermuirs, prolonged into Ireland, is North-East and South-West. This corresponds with the general direction of the slaty rocks of Cumberland, the Isle of Man, North Wales, and Cornwall, of the Hundsrück and Taunus. But the direction of the Devonshire slaty rocks is nearly East and West; so is that of the South of Ireland, the Harz, the South-West border of the Vosges, and the Bocage in Calvados. M. de Beaumont thinks these two directions belong to two periods, the latter being more recent. This *may be* true; the hypothesis is not destroyed by the discrepancy, but we must demand clearer evidence of its truth.

The second system is more accurately limited than the former, since the series of rocks dislocated is generally more complete, and the undisturbed strata are of nearly the same antiquity. Three prevalent directions are recognised. The first is nearly North and South from the course of the Tyne to that of the Trent; it is parallel to the axis of the vale of Clwydd and to the chain of the Malverns. The second is nearly East and West, in South Wales and the Mendip hills, and along the Tyne; West North-West and East South-East in Charnwood forest; West North-West and East South-East in Craven; East and West in Belgium; East North-East in the valley of the Meuse and Westphalia; North-East and South West, or North-West and South-East in Shropshire and Radnorshire. The third is North and South, or North-West and South-East, from Basle to Mayence.

Some of these cases of discordant direction occur along the same dislocation, as, for instance, the great Belgian axis of disturbance from Westphalia up the Meuse and through France to Boulogne; in other cases the difference of direction *may* correspond to a difference of age: but this has not been proved, and ought not to be assumed.

Dislocations known to be of different ages.

We may now turn to consider the relative directions of dislocations of different ages. M. de Beaumont himself has found several instances of dislocations of unequal antiquity following the same parallels of direction. The North-East and South-West direction of the first system of disturbance is repeated in the fourth. (Seventh of De Beaumont.) The North and South direction of some dislocations of the second system (third of De Beaumont) is repeated in the seventh. (Tenth of De Beaumont.) We shall add some other coincidences. The East and West direction of the South-Wales coal field is the same as that of the great fractures along the Isle of Wight; the great Cleveland dyke of 70 miles in length, which cuts the oolites, is nearly parallel to the older elevation of Charnwood and the great faults in Craven. Again, it is a general law of most mining districts to have their principal productive veins running nearly East and West, and crossed by others North and South. Is it to be supposed that veins which are parallel are universally of the same age? Is it not very well known that they are not so?

These difficulties seem wholly insuperable in the present state of the Science. It seems not possible from elements so uncertain and confused to rise, by a legitimate process, to any sound conclusion, at once exact and universal in its application. Any hypothetical connection between geodesical lines and the directions of disrupted strata appears liable to interminable difficulty, from the excessive number and various direction of the dislocations. Any line drawn through any Country, not far removed from a great axis of disturbance, will be found more or less parallel to some of the cracks or faults which depend upon that axis. If, rejecting these minor phenomena, we limit our evidence to the great lines of mountains, the data are too few and too disjoined for satisfactory induction. To show by what evidence M. de Beaumont has himself been led to adopt his hypothesis, we may abstract his original account of two systems of disturbance, the one detailing minute, the other more general evidence.

Seventh system of De Beaumont.

Three small granite eminences in the Côte d'Or, near Sombernon, which accompany the disruption of Jura limestone there, range in a line North-East and South-West, parallel to the summit ridge of the Côte d'Or. The line of these granite points being considered part of a geodesical circle, and prolonged in each direction, is found to coincide with several remarkable geological accidents or disturbances. In the North-East, for instance, it coincides with dolomitic Jura limestone and steep dips at Suxy, between Langres and Dijon, with the hot springs and magnesian muschelchalk of Bourbonne les Bains, with the basaltic eminence of Essey, South of Luneville, and with the granitic protuberance of Albersweiler, between Annweiler and Landau.

Another line of disturbance parallel to the preceding is indicated, and it is observed, that from Paray (Saone et Loire) to Plombières, (Vosges,) the great line of valley watered by the Bourbonne and Saone is perfectly parallel. This line prolonged into Germany passes along the line of the valleys of the Mayn and the Saal, through Mittenberg to Leipzig, and is parallel to the Erzgebirge and Mittelgebirge.

Now all these dislocations were probably produced at the same geological epoch, which, though inferred from the general phenomena along the line, is determined more exactly in consequence of an extension of this system of faults by a series of parallels retiring to the South-East, till we arrive in the Department of the Rhone, where the Jura limestone and chalk occur together, the former dislocated, the latter undisturbed. The direction of these parallels of disruption is at Dijon, North-East and South-West. In the Jura a great number of undulations in the strata range parallel to a line North 40° East, or North 45° East, and, being sometimes filled with green sand deposits, are clearly of the same date as the other disruptions mentioned above.

The insulated chain of the Pyrenees, one of the most

Ninth system of De Beaumont.

remarkable in Europe, forms the base of the ninth system. Many observations prove that the chalk and green sand are here uplifted with the primary rocks, but the later tertiary deposits lie level against their slopes, and some were deposited from a sea which washed the base of the already elevated mountains. The general direction of the chain, from Cape Ortegal in Galicia, to Cape Creuss in Catalonia, is a little South of East; but this general chain is composed of partial ridges whose axes are parallel to one another, and directed West North-West and East South-East.

This direction belongs to the disturbances of the same date in Provence and near Nice, and is recognised in the Apennines, at least in the Northern part, and in the Country of Naples, and along the South shore of Sicily. The South-Western boundary of the Nägelflue, in Swisserland, appears to correspond with the Pyreneo-Apennine line, as do likewise the Dalmatian and Croatian summits, the valleys of the Save and the Drave, the line of the Rhodopean mountains, and the ridge which crosses the Straits of the Bosphorus. Similar directions seem to be traceable in Greece; and as far as the evidence yet collected goes, the date of the elevation of all these chains is the same. The Carpathian range, parallel to the Dniester, falls into the same system with a small line of granitic and syenitic rocks along the Elbe near Dresden, and the mean courses of the metallic veins of the Harz.

Extending his views, M. de Beaumont finds some traces of the Pyreneo-Apennine system in Africa and Syria, in the Caucasus and the Ghauts of India; but the imperfect state of information concerning the Geology of these Countries renders the inferences concerning them of less value than those which relate to the North American mountains. On prolonging the Pyreneo-Apennine circles across the Atlantic by Hecla and Greenland to the New World, we find it descend parallel to the Alleghanies and their Northern connections, which have determined the form of the Eastern shore of North America; and, as appears by the statements of Transatlantic Geologists, were probably uplifted between the age of the chalk and the latest of the stratified rocks.

Such remarkable accordances of epoch and linear direction, over so enormous a length upon the surface of the Globe, cannot, says De Beaumont, be the result of chance, but of a regularly acting internal cause. Those who admit the generalization, usually imagine the effects to depend upon periodical fractures of the crust of the Globe through the cooling of its interior, so that the crust contracts convulsively with lines of fracture parallel to some great circle of the sphere.

More limited inquiry.

Relinquishing for the present any further attempt to construct a general system of relation between the age and direction of dislocations, we may still find it useful to inquire what laws of direction belong to dislocations in a limited district.

The remarks already made, pp. 543, 544, 597, 598, and in the Section on Mineral Veins, will render it unnecessary here to do more than state a single case of the parallelism of trap dykes, which has been furnished by Archdeacon Verschoyle, in the North-West part of Mayo and Sligo. (*Proceedings of the Geol. Soc.* 1833.) He describes no less than eleven basaltic and amygdaloidal dykes, which, in a space of 11½ miles in breadth, traverses the Northern part of the district in a nearly East and West direction, and cut through all the formations from the gneiss to the carboniferous limestone. One of these dykes he traced between 60 and 70 miles, and believed it might be followed much further to the Eastward. Two of the dykes are crossed by others having a North and South direction.

Direction of the Strata.

Mitchell's views.

It was long since remarked by Mitchell, that the direction of the strata in any region was generally parallel to the ranges of mountains; a truth of great importance in the modern system of Geology. The prevalent range of the strata in any Country must, however, depend partly upon another circumstance, *viz.* the original line of the Ocean boundary. In many parts of the Globe the most prevalent direction of the strata is observed to be North-East and South-West. Humboldt was so struck with these *loxodromic* lines in Europe, that he says one of his principal inducements to visit Equinoctial America was to examine the directions of the strata there. He has furnished evidence that the parallelism of the strata to the great lines of mountains, is a general law of Nature.

M. Necker's inferences.

M. Necker, in a communication to the *Société d'Histoire Naturelle de Genève*, has shown a very unexpected coincidence over large portions of the Northern hemisphere, of the direction of the strata, and the curves of equal magnetic intensity, as traced by Captain Sabine. One of these curves, that of 297 seconds, traverses Scotland in a direction North-East and South-West, which is exactly that of the strata; it keeps the same direction by Christiania in Norway, where, according to M. Von Buch's observations, the strata trend North-East and South-West, and pass through Sweden, where, according to Hisinger, the same direction of strata predominates. On arriving at the Gulf of Bothnia the magnetic curve turns North-West and South-East, which, according to Strangways, is the direction of the Southern border of the Swedish and Russian granite.

The curve of 308 seconds enters Europe by Lisbon, and passes South-West and North-East through the Spanish Peninsula, which is nearly the line of most of the long Sierras between the great rivers; it passes by the Cevennes, and goes parallel to the Alps in their North-East course to the Tyrol, but there turns South-East, as do also the lines of stratification through Carniola, Istria, Croatia, Dalmatia, and the Morea. Parallel to these are the Carpathian mountains. The same correspondence between the magnetic curve and the lines of strata is traced through the Crimea and along the Caucasus.

In North America the magnetic curve and the stratification range North-East and South-West along the whole Eastern coast; in the Rocky Mountains both extend from North North-West to South South-East: in Mexico the magnetic curve takes the parallel of the Cordillera of Anahauc North-West and South-East, and ranges along the South coast of New Spain. Further to the South the curves resume their course North-East and South-West, which, according to Humboldt, is the direction of the strata in Venezuela, and between the Orinoco and the Amazons. The mighty chain of the Himalaya, which in Nepaul bears North-West and South-East, and turns North-East at the North-East extremity of Bengal, is parallel to the curve of 297 seconds which was first noticed.

These remarkable accordances deserve the attention of Geologists, who must always receive with particular gratification any results tending to connect the general facts of the construction of the crust of the Earth with the laws of the distribution of terrestrial magnetism, electricity, and temperature.

Effects of Convulsions in altering the Relations of Land and Water.

The submarine origin of the whole stratified crust of the Earth being admitted, and the actual elevation o these rocks above the sea in the existing continents being known, it is required to determine the several geological periods when different parts of the solid land were raised above the waves. It is usually taken for granted that this effect has been produced by the several systems of convulsions which have impressed angular movements upon dislocated portions near the surface of the Earth, and thus raised some portions and, perhaps, depressed others. That this general impression is frequently well founded, though it does not embrace the whole truth, will appear from the simple consideration, that the whole configuration of the dry land, whether in islands or continents, is dependent upon the direction and elevation of the chains and groups of mountains, which were certainly elevated, at various assignable geological epochs, above the ancient sea.

It may be asked how is this ascertained? The mere fact of those mountains being convulsed, and the strata therein thrown into angular positions, does not seem to prove that the region was elevated by such action above the level of the sea, nor, perhaps, that it was uplifted at all; since it may be imagined, with some theorists, that the neighbouring parts were depressed, and that the general level of the Ocean has been lowered. In answer to this we may proceed to show that the effect of the convulsions was relatively to raise the convulsed parts; that these parts were in several instances elevated above the sea at assignable periods; and that these effects were independent of any imaginary depression of the general level of the Ocean.

Elevation the consequence of convulsion

That the effect of convulsions has been, generally, to raise the convulsed parts will appear shown by considering what is the focus of the disturbance and the direction of its energy. The mountain chains and groups are most certainly the foci of the disturbing forces; for as we pass towards them, from all sides the number and force of the dislocations continually increase, and the declination of the strata grows more and more violent. The direction of the disturbing force is by the same process of observation clearly discovered to be vertical or nearly so, and outwards from the central regions of the Earth. It was an expansive force, which employed its principal efforts along certain lines and about certain centres, there breaking and bending the strata in the highest degree, but also lifting them up on all sides around. As far as we can judge, this elevation of the mountain chains and groups was generally unaccompanied by any neighbouring depression, for the inclination of the strata for the most part gradually subsides to a gentle slope, and finally vanishes in nearly horizontal planes. In the mountain chain itself, various and suddenly reverted dips may be met with corresponding to the violence of the disruption, but by a careful study of the exterior slopes the general tendency of the convulsion may be clearly deciphered.

The same data will not, however, by any means give us right to conclude that the mountains so uplifted were raised above the sea, because, though we may know the absolute height of the vertical movement, this will avail us nothing in our ignorance of the original depth of the water. We must examine to see whether they bear on any part of their surface any traces of those later marine deposits which spread around their bases. If they do, we may be sure they were not elevated above the sea till after the date of these strata; as for instance, the Alps, which bear upon their crests portions of oolitic, cretaceous, and tertiary strata, are thus proved to be of modern elevation. If they do not, and the newer marine strata around their bases have been deposited horizontally against the slopes of the mountains, we are entitled to believe that these had been previously reared above the sea. This conclusion, however, it must be always borne in mind, does not inform us correctly to what height they were reared above the sea, but leaves us to infer that they have since partaken of another movement by which these newer strata have been placed at their present elevation.

Speculations on the Ocean level.

The facility of escape from many embarrassing considerations which a general depression of the level of the Ocean seemed to offer, was too tempting to speculators in Geology to permit them to inquire into its physical probability. The simple question of what has become of the vanished water was disregarded by Werner, and perhaps never thought of by his followers. It will not now be sufficient to press it into a subterranean abyss, nor to carry it off to other planetary regions in the tail of a comet; we must admit that the quantity of water upon the Globe has been constant, or give up all pretence to philosophical moderation; and with this restriction upon our inquiries it becomes easy to prove that the level of the Ocean is confined within very narrow limits of fluctuation, so long as the Earth's axis and rotatory velocity are supposed invariable. If the level of the Ocean be expressed either by taking its mean depth, or the mean radius of its surface, this level may be supposed variable by reason of any local convulsive movements of the dry land or bed of the sea, any change of dimensions of the whole Globe, or any alteration of the mean temperature of the water. First of temperature. If we take the mean temperature of the Ocean at the Equator 81.5 F. its temperature at the Poles 0.0 F. on the surface, and at some depth (d) 81.5 F.; and suppose, in conformity with inferences from organic remains, that the whole surface of the Globe was formerly subject to a temperature equal to that of the Equator; the Ocean at that period must have been defined by a longer radius.

Variable with change of temperature.

The expansion of the Polar waters, supposing them to have been fresh, would be at the surface only to the extent of 4°.0, because at temperature 0°.0 F. fresh water occupies nearly the same space as at 77°.5; at nearly half the depth (d) it would expand through 42°.75, at the depth (d) nothing. Average expansion = 22°.4 which corresponds to $\frac{1}{184}$ of the depth. If we suppose d to be 10,000 feet, the Polar expansion = 54 feet. But if we suppose the water to have been salt, the expansion at the Polar surface, from 0°.0 F. to

$$81.5\text{ F.} = \frac{81}{180} \times \frac{1}{20} = \frac{81}{3600} = \frac{1}{44}\text{th}$$

of the depth: and at other latitudes

$$= \frac{1}{44} \times \text{sine lat.} \quad \text{And } \frac{10000}{44} \text{ feet} = 228 \text{ feet},$$

which would give a mean rise of the Ocean = 76 feet.

It is evident that such fluctuations of level, however real, are not adequate to explain the desiccation of large tracts of land.

What might be the effect of a general change of dimensions of the Globe, through variation of its own temperature, is beyond our power of investigation, because we do not know in what ratio the solid and liquid parts of the Globe would alter their dimensions.*

We may, however, consider the effect of a general change of dimension of the nucleus of the Globe, supposing the superficial temperature unaltered. According to all analogy of organic forms, the Globe may be supposed to have grown cooler continually, and thus to have contracted in bulk; but this, by shortening the mean radius, would cause the Ocean level to *rise* upon the land, which is contrary to the effect we wish to explain. If we even allow, for the sake of argument, an augmenting diameter to the Globe, this must go to a very great amount before the level of the Ocean, as compared to the land, would be sensibly affected. If the Ocean be 5 miles deep, the diameter of the Earth must be augmented 1½ miles to cause the level of the water to sink relatively 10 feet, and to sink it half a mile the radius of the Ocean must augment 400 miles. It is unnecessary to prosecute this inquiry, for a sinking of half a mile would be insufficient for the desiccation of the whole dry land, even allowing the great mountains to have been uplifted.

Variable through intestine movements.

The most interesting part of the inquiry remains to be more carefully examined—the variability of the Ocean level in consequence of displacements of the solid land. We shall put the case in three forms, and according to each of these imagine the present continents to be depressed beneath the waters of the Ocean, as they once certainly were.

First, we may suppose no vacuum to exist below the crust of the Earth, nor any receptacle occupied by air or gases into which the solid land could sink, but that a sinking in one place should be compensated by a rising in another, so that the cubic dimensions of the Globe should remain unchanged. Moreover, to put the case to extreme, it may be a condition that the land shall sink so that water shall cover the whole surface. In this case the level of the Ocean would rise, that is, the mean radius of its curved surface would be lengthened, by a quantity depending on the mass of the solid land submersed, and on the relative area of land and water. This relation of area is about as 3 water to 1 land. The cubic content of the solid land may be thus estimated. In England, Wales, and Scotland, the average height of those conspicuous mountain masses which appear to give shape to the whole country is about 3000 feet; and if we consider this as the apex of a cone whose base is the given area, we shall have the cubic content of the mountain masses $= \frac{3000}{3} \times$ area. But on acccount of the valleys this quantity must be reduced to half, or $= \frac{3000}{6} = 500$ feet, and the area $= \frac{1}{4}$ of the whole area of the Island. In addition, the more level parts may be compared to a mean cone of 400 feet altitude, on an area $= \frac{3}{4}$ the whole area of the island. Then $\frac{400}{3} = 133$ feet, and making the sum of the bases = area of the Island, we have mean altitude $\frac{500 + 400}{4} = 225$ feet.

This principle applied to the Continents of Asia and America would give in round numbers about 1000 feet mean altitude of land; and as the area of the expanded Ocean would be four times as great as the land is now, the total mean elevation of the water, by the submersion of the whole mass of land, would be about 250 feet: a quantity too small to be of use in explaining any but the lesser order of geological phenomena, and which may be considered as the extreme limit of oceanic rise.

Secondly. We may suppose the existence of cavities into which the solid land might sink, so that there may be no elevation in another place corresponding to the given depression. To put this also to extreme, we may imagine the very improbable case that a mass of solid materials equal in bulk to all the solid land above the water, should sink into a cavity, and that the surface of the submerged land should be level. The level of the Ocean would be nearly unaltered, except in a small degree, by reason of its shallow expansion over the area of the land. We might go on to suppose even the enormously improbable case of cavities existing so large as to admit twice the whole solid mass of the continents, and that these should sink with an equal bulk of materials into these cavities. Even in this case the Ocean level would only be lowered 250 feet.

Thirdly. If we suppose contemporaneous or successive elevations and depressions however extensive, the Ocean level would oscillate about a constant line.

Conclusion adopted.

It is evident, therefore, that by no stretch of conjecture, that is not absolutely monstrous, can we torture the known laws of terrestrial arrangements into agreement with the hypothesis of any but small changes of the level of the Ocean; a conclusion of the highest value, since it enables us to argue upon that level as a general standard to which we may refer all the effects of internal movements, in whatever period, and by whatever forces produced. It must be remarked, however, that it fixes no limits to the effects of the temporary violence induced in the Ocean by such movements, because these effects would be proportioned to the impulse with which they were attended.

Gradual elevation of land.

It appears that we cannot in all cases understand the possibility of the elevation of land *out of the sea* by the mere effect of local convulsive movements, but must in addition admit the gradual rise of large tracts of land whether convulsed or not at some earlier epoch." England is an unexceptionable example; and probably every Country will be found to require the same admission. The necessity for admitting this gradual elevation of the whole country, is first suggested by the difficulty of otherwise accounting for the altitude of the tertiary and other marine strata, which have been deposited long since the great convulsions which partially or completely raised the primary and other old systems of rocks, and are, in general, remarkably free from the traces of any such events. The older Geologists relieved themselves from this dilemma, by inventing the gradual diminution of the level of the Ocean; the moderns meet the difficulty by supposing a gradual intumescence of the land. The former mode has been proved to be incredible, the latter we certainly do not yet understand, but it is not at variance with the established facts of convulsive elevation.

Where convulsive movements can be traced in their effects we have a good local cause for the local elevation of the ancient bed of the sea; but where no such movements can be traced, and yet the land is raised far above the sea, it is clear that we must neither admit convulsion, nor deny the relative change of level of land and water. Now the areas of country which are elevated, but not convulsed, in such a way as to account for this elevation, are very extensive. The greatest portion of the level regions of the Globe is thus circumstanced. In many instances we might plausibly explain the facts by supposing that the same localities (as mountain chains and groups) which had been in very ancient periods liable to great convulsive movement, were during later periods influenced by more gradual and continual subterranean expansion, so as to bear up on their slopes the newer strata formed and in process of formation. This would apply to England, whose great centres of old convulsions are nearly confined to the Western borders, and it seems equally suitable to most Countries whose lines of mountains correspond with the general figure. The principle, once admitted however, will be found applicable to all situations, and equal to solve a very difficult class of problems in Geology. It may even clear our way through cases of alternate elevation and depression, such as the Temple of Serapis on the Neapolitan shore: for whatever be the cause of local intumescence, it may be discontinuous or intermittent, and elevation in one quarter may be counterbalanced by depression in another.

---

* Since this Section was written, Mr. Babbage has made known some very interesting views bearing on this subject. (*Proceedings of the Geol. Society*, 1834.)

Proposal of a hypothesis on this subject.

But is such an assumption of local subterranean expansion consistent with what is known of the interior constitution of the Globe, or is it a vain speculation? So little is known of the interior of the Globe, that almost any hypothesis is safe from coming into collision with that knowledge, provided it allows of given mean density, and a specific gravity increasing toward the centre. Newton supposed the spheroid to be homogeneous; it has been found that this supposition is by no means necessary to fulfil the observed conditions of the problem of the Earth's figure, and the irregularities of attraction indicated by the pendulum experiments, and of curvature by direct meridional measures, seem to show that the *concentric masses* of the spheroid may *not* be of *uniform* density.

This being allowed, there would seem no objection to suppose that the densities along any one *radius* of the spheroid are *variable*, by reason of intestine movements among the unequally dense parts of the concentric masses, and this would exactly answer the conditions of the geological problem. For the length of any radius of the heterogeneous spheroid would necessarily vary with the densities; and considering the small proportion of the height of the land above the mean radius of the latitude, it is clear that small internal changes in a length of 4000 miles would easily account for variations on that line to the extent of 1000 feet or yards.

This *hypothesis* would give a gradual and prolonged elevation in some parts and corresponding depressions in others; it would not affect in a sensible degree the astronomical elements of the Planet, but would change more or less completely its hydrographical boundaries. It appears consistent with the inference to which we were conducted while studying the phenomena of mineral veins, (p. 777.) *viz.* that under the same region of stratified rocks different sorts of igneous rocks had been at different times developed; and at all events may be used as a first contribution toward a sound mathematical theory of general subterranean movements independent of volcanic convulsions.

We may now attempt a brief sketch of the relations of land and water in particular regions, during the successive geological periods, and notice the character of the agencies concerned in producing them.

It is sufficiently evident that we are precluded from any attempt to assign these relations generally, because we cannot know what tracts of land were once raised above the sea, and have since been submersed. This applies with great force to the periods, whatever they were, which preceded the formation of what we call primary strata; for concerning the question of the existence of land during those periods we cannot even offer a conjecture, except upon the basis of inquiries into the remains of terestrial organic forms imbedded in these strata. The evidence which they afford negatives, as far as it goes, the existence of land plants; but it is chiefly by the great extent and uniformity of character of these deposits, and by the absence from them in the lower parts of marks of littoral or fluviatile action, that Geologists might justify a belief that little or no dry land divided the wide primeval Ocean. We pass to consider the state of things during the primary period.

During the primary period.

It is admitted that the greatest effects of the elevatory movements which can be traced in the existing ranges of mountains were posterior to the primary deposits; but there are good grounds for believing that dry land in some (unknown) situations began to furnish vegetable reliquiæ, during, perhaps, the whole of the period occupied in the deposition of the clay slate system. *First*, there is the certainty that some disturbing effects of igneous agency are traceable among very old members of this vast group of rocks. (p. 571.) *Secondly*, the existence of carbonaceous matter (anthracite) among the newer slates. *Thirdly*, according to different authors, in the upper parts of the series occur various land plants.

At the commencement of the carboniferous epoch.

It is highly interesting to observe the coincidence of two classes of results bearing on the relation of land and water at this epoch. Some of the most extensive and important physical features on the Western side of the basin of Europe have resulted from convulsions *preceding* this epoch, which certainly raised out of the sea many remarkable ranges of high ground; and the most considerable accumulations of land plants which have furnished the substance of coal in Europe and North America, *followed* those convulsions. It may, perhaps, eventually be possible to derive, from the comparison of the local centres of elevation with the limited fields of coal, some conclusions as to the place and other circumstances of growth of the vegetables; at present we shall only venture three remarks. 1. The deposit of coal plants does not in general follow immediately, but after some interval, the uplifting of certain tracts of land; for between the uplifted primaries and the phytiferous secondaries, great thicknesses of conglomerates holding few or no plants, and beds of limestone full of marine shells intervene. 2. The plants which most predominate in the older parts of the carboniferous deposits in Great Britain (coniferæ) appear like the vegetation of a mountain district in a warm climate, while those which abound in the younger deposits of the same period (cactiaceæ, equisetaceæ, &c.) may be more successfully compared to plants of plains and marshes. 3. The coal basins appear related in position to the ranges of primaries uplifted before the deposition of coal, and not to those of subsequent ages. This is an important fact, and must be further developed. On the Geological Map of the British Isles, (pl. i.) the local relation of the primary and carboniferous strata may be seen, and it will be observed that the latter form a broad belt parallel to the general course, entering into the indentations, and surrounding the insulated eminences of the former. But along the ranges of the Alps and Pyrenees, no such bands of carboniferous rocks occur. The British primaries were uplifted *before* the carboniferous period, the great European ranges *after*. Coal is, however, not uniformly spread over all the area of the carboniferous rocks. It occurs in the great valleys of the Forth and Clyde, *between* the Grampian and Lammermuir ranges, *in* valleys of the Lammermuir; (Sanquhar;) *round* the Cumbrian mountains; *round* the Welsh mountains; *in* hollows of the Anglesea primaries. Besides these remarkable juxtapositions, the long range of the great Northern coal fields is still partially united with the coal deposits encircling the Cumbrian and Welsh mountains; and it is only by the effect of immense subsequent convulsions, and the consequent unconformity of the saliferous formation, that it does not now appear completely united with them.

The immense coal deposits of Ireland are in the same way surrounded by primary strata, which were raised above the sea before the accumulation of the coal. Parallel to the Hundsrück and to the Taunus and Ardennes, which were elevated about the same early period, lie the coal deposits of Saarbruck, the Netherlands, and Westphalia. Comparing this statement with the inferences concerning the growth of the plants of the carboniferous period, (p. 594—597,) and with the peculiarities of the several coal fields, we seem to find a fair basis for reasoning concerning the original habits of fossil plants, which may eventually lead to important results.

Before the saliferous epoch.

The elevatory movements consequent upon the deposition of coal appear to have been very general and extensive, and in the basin of Europe to have materially contracted and altered the boundaries of the sea. In England, especially, this effect is clearly shown, by the rising above the sea of the large tract reaching from the Tweed to the Trent, and including nearly the whole of the space between Berwick, Carlisle, Liverpool, and Nottingham; thus forming a large and nearly united tract from the Pentland Frith to Cheshire. To the same periods we must refer a large augmentation of the previously elevated regions of Wales. It will thus appear that nearly all the Northern and Western parts of the Island of Great Britain were then raised above the sea, which still flowed over the sites of all the Midland, Eastern, and Southern Counties. The greater part of Ireland had also emerged. Besides these greater elevations, some smaller tracts, which now appear as detached groups of mountains, were then conspicuous as islands. Charnwood forest, the Dudley district, and Mendip are examples. The Cumbrian mountains were half surrounded by a sinuous arm of the sea, which washed the feet of the Penine chain from Kirkby Stephen to Brampton, expanded into the Southern Counties of Scotland, and perhaps connected itself along what is now a part of the Irish Sea, with a great diversified gulf in Cheshire, Warwickshire, Leicestershire. (See Map, pl. i.) To the East of a line drawn from Newcastle through Nottingham to Exeter, we may suppose it to have been all an open sea as far as the Ardennes and the Harz. It thus appears that some of the marking features of British and European Physical Geography are of very high antiquity; and however modified in detail, by subsequent internal movements and superficial wasting, their larger proportions and general effect in those early periods may be very well judged of from the characters which they retain at present.

It might appear that, during the saliferous period, the elevated lands nourished no great profusion of vegetables; for throughout the whole of Great Britain the magnesian limestone and new red sandstone system is wholly, or very nearly so, devoid of such remains; and though in a few places in Germany plants are found in some parts of this system, they rather confirm than oppose the general inference.

It does not seem possible to trace any close dependence of the local character of the saliferous system upon the circumstances of the Physical Geography of the region; for, correctly speaking, there is very little of *local* character, except what is imparted by the unequal extension of the limestone groups; and these are probably wholly derived from marine decompositions. Along the Vosges mountains, perhaps, a peculiar sandstone conglomerate may have been derived from these mountains.

Scarcely any thing in Geology is more remarkable than the great uniformity of appearance of such extensive deposits as those of the saliferous system, with such few remains either of marine or of terrestrial reliquiæ. The prevalent red colour of this system is of itself a circumstance of great interest, though of unknown origin. In many cases this colour is derived from a superficial coating of oxide of iron round the internally clear quartz grains; and there can be no doubt that chemical agencies were then in operation of a very extensive and very remarkable kind. It is difficult to avoid believing that the life of the marine mollusca and radiaria was much controlled by these agencies.

Before the oolitic epoch.

The deposits between the coal system and the tertiaries succeed one another so regularly in England, and even throughout Europe, that it is perhaps impossible to explain the successive parallel outcrops of the several strata, except by supposing a gradual elevation of the pre-existing land, or a gradual retreat of the Ocean. This problem becomes, however, still more intricate when we add the following general truths: 1. That in England the oolitic strata, which succeed the red marls, form hills of greater height than *any one point* of the saliferous formation; the same is true for Germany and France. 2. That there exist beyond the general range of the oolitic outcrops, many far detached hills of these strata resting on and overlooking broad plains of red marl, which seem to be in an undisturbed position. It is obvious in these instances that the surface has been subjected to enormous waste by the violence of watery currents; in every theory of diluvial or alluvial action it is supposed that these denudations were performed upon the dried and elevated land; but few speculators have had the boldness to attempt the solution of the difficulty, by assuming that the *inversion of relative level* between the red sandstone and the oolitic systems is wholly due to the wasting action of water.

Perhaps we shall best consult the true interests of the Science by not insisting much upon any mode of accounting for these yet insufficiently examined questions; but it seems right to observe, that a gradual elevation of the South-Eastern parts of England, parallel to the line of the oolites, and prolonged in duration through the whole period of the saliferous, oolitic, cretaceous, and tertiary rocks, would fully agree with the general physical features of the surface of the district, the minuter inequalities of which may certainly be ascribed to superficial watery action. This view appears to agree well with the general character of the upper saliferous, oolitic, and cretaceous deposits, which exhibit many repetitions of analogous rocks and fossils, many deposits of limestone and clay, such as might be formed in quiet or deep waters, with but few beds of sandstone. From some of these local sandstones we learn the fact, that some parts of the land which borders the oolitiferous sea, nourished a variety of plants, characterised upon the whole by a predominance of vascular cryptogamia and coniferous phanerogamia, different from those of the older coal tracts.

Effects of Convulsions on the Deposition of Strata and on Organic Life.

The formation of extensive conglomerates has been already shown to be a natural consequence of convulsive movements; and it is in some cases very probable that the disturbance was centred in the immediate vicinity of these accumulations. But it would be a gratuitous contraction of a very interesting field of research to limit our inquiries into the effects produced by subterranean movements on the deposition of strata, if we did not take into consideration the peculiarities of mineral character belonging to the several systems of marine deposits, the alternations of marine and fresh-water rocks, and the successions of races of organic beings. What dependence there may be between these phenomena on the one hand, and subterranean movements on the other, will undoubtedly be revealed by the progress of inductive Geology, and results of a very interesting kind will flow from such a discovery. At present, we can only sketch a dim outline of a subject as yet scarcely emerging from obscurity.

Mineral Characters of the Systems of Strata.

Actual process of nature.

Sedimentary deposits, whether they are occasioned by the action of streams and floods from the land, or of tides and currents in the Ocean, have a mineral character depending on the nature of the materials acted upon. The same great stream may, according as its different feeders predominate in their action, deposit materials of different quality; there may be in such deposits effects depending on the season of the year, but all such differences are periodical, and a series of alternations of given mineral aggregates is the result.

The action of the tides in a certain direction, is also liable to periodical variations of intensity; the coasts worn by tides may be unequally affected at different times, and the accessions of materials from the land may be irregular; still these minute inequalities are almost wholly lost when we contemplate the average results of a long-continued course of the same tidal action.

Deep-sea currents, so long as they follow the same channels, can hardly be supposed to produce any but very uniform admixtures of sedimentary ingredients.

When, therefore, we find a series of sedimentary strata to consist of repetitions of the same materials, or of recurring alternations of different materials, the whole is reasonably referred to a series of the same, or similarly alternating effects of watery action upon the same tract of land, the same line of coasts, or the same channels of the sea.

On the contrary, the suppression of one class of deposits, and the production of another, clearly marks out to us that the water has ceased its action on the land, coast, or Ocean bed, which it formerly wasted, and transferred its attacks to a new quarter.

It was not the perception of these simple laws of modern nature but a clear recognition of their effects in older periods, that led Geologists to agree in classing together portions of the innumerable layers or strata into certain groups or formations, according as they are identical or analogous in their nature, very gradually change from one to another, or consist of a series of recurring mineral terms; and in dividing these groups at the points where new terms appear and old ones are suppressed. Thus the suppression of red marl, and the introduction of blue clays, marks the boundary of the saliferous and oolitic formations; the suppression of oolite, and the introduction of green sands, marks the limit of the oolitic and cretaceous formations.

No universal strata.

Whatever view we adopt of the origin of sedimentary rocks, there can be no doubt that, even from the earliest geological period, the bed of the sea must have been composed in different regions of different materials; this must have been the case, even if we carry back our thoughts to that remote epoch where we may suppose that nothing solid existed at the surface of the Globe, except the products of heat; for these, in fact, contain nearly all the varieties of minerals, and nearly all the elements of the composition of stratified rocks. The very earliest formations which we have yet succeeded in tracing, exhibit themselves in two very distinguishable masses; the gneiss and mica schist system on the one hand, and the clay slate system on the other. When, by the partial elevation of these rocks above the level of the sea, the Ocean was divided into separate parts, local differences of the sedimentary, and even chemical deposits, must speedily have resulted; and as the extent of land increased in any particular region of the Globe, the deposits in the residuary seas thereabout must necessarily have become more and more dissociated from those of other regions.

It is, therefore, very evident that there can be no universal strata; that during the greater part of the geological periods, rocks of very different nature may, and, indeed, must have been contemporaneously deposited; although, according to the circumstance of the cases, the peculiar products of one region may have been, by oceanic currents or other causes, mixed with those of another, and so a continual or interrupted analogy between the series of strata in each maintained.

Changing sediments connected with subterranean movements.

We have now arrived at the point when the coordination of the diversity of sedimentary aggregates in a given oceanic basin with subterranean movements, and the dependence of the former on the latter, may be presented in the form of a very probable inference. Geologists have long been accustomed, while reasoning on the phenomena of tertiary rocks, to recognise the principle of the dependence of the local difference between contemporaneous strata in different basins upon the physical structure of the region from which the materials of these strata were derived. It has been already shown that the successive diversity of strata in the same basin can only be understood by admitting that the different sediments were brought from different regions; it is evident that for this end the drainage of the land, the flow of the tide, or the direction of oceanic currents, must have been changed; this can only be ascribed to an alteration in the local relations of land and water, that is to say, to subterranean movements.

When this change of the sedimentary deposits is sudden and complete, we may generally feel assured that it is owing to violent subterranean movements, which have opened a new communication with the basin; the exact *site* of the centre of convulsion may perhaps not be ascertainable, though in some particular instances the *direction* of the new currents may be inferred, and thence their local origin conjectured. When the changes of sediment are gradual or alternate, we must apply corresponding inferences with greater caution.

In some cases slight movements might accomplish great changes in the nature of the deposits. The map of the terraqueous Globe shows us how easily, at particular places, the waters of different oceanic *alvei* might be brought into union by the lowering of an isthmus or the opening of a strait. If the Mediterranean were connected through the Red Sea with the Indian Ocean, would not the deposits in each of them be reciprocally influenced? Such internal movements as might occasion this appear trifling when compared to the disturbances which we know to have been many times effected within the range of geological chronology.

Successive Races of Marine Animals.

Local change of organic races.

If, in consequence of internal movements, a given basin was opened to the reception of currents and sediment from a new quarter of the Ocean, it could scarcely happen otherwise than that a change should arise in the inhabitants of that basin, by the extinction of some, and the introduction of other species. If we except the earliest series of fossiliferous deposits, there is nothing in Geology to indicate that the distribution of species over the Globe was regulated by different laws from those which now prevail; the superficial temperature of the Globe was perhaps more equable, and for this reason organic forms might be more extensively distributed, there might be *less* local distinction than at present, but yet each species had its definite boundaries, and different regions were characterised by peculiar races.

Upon the establishment of a communication from one such region to another, there must necessarily be a *tranference* of organic life, at least in one direction, according to the locomotive habits of the creatures, and the influence of currents upon them and their ova, and other circumstances.

It was with this in view that the passage (p. 553.) relating to the succession of races, corresponding to successive deposits, on a given part of the Ocean beds, was written.

How remarkable is the coincidence of great convulsions, decided changes of mineral aggregations, and substitution of new organic remains, needs only to be mentioned; for these three orders of effects are all combined in modern Geology to characterise the groups or systems of stratified rocks.

Fresh-water and Marine Alternations.

Few geological phenomena declare more plainly their dependence upon ancient convulsions than the alternations in a given basin of strata, of fresh-water and marine deposits. Not that in every case where we see fluviatile or even lacustrine shells alternating with marine exuviæ, we must suppose the levels of land and sea to have been changed, because at the mouths of some rivers this might happen from the bursting of a lake, a violent inundation, or even the natural course of things; but when, as in the coal field of Yorkshire, over the marine deposits lies a great mass of matter derived from the land, and in this a particular layer of marine exuviæ; when, as in the Weald of Sussex, we observe above the marine deposits of the oolites a great thickness of fluviatile deposits covered by marine green sands; or, as in the Isle of Wight and the basin of Paris, see really lacustrine marls and limestones interposed among really marine strata; the conclusion seems inevitable that these are effects of changes in the relative level of land and sea. It would, however, be too much to assert in every case that the internal movements *were centred* near the places where we witness some of the effects; on the contrary, we may perhaps probably often be merely looking upon the consequences of convulsions which happened at great distances of space, and which produced near their centres of action wholly different phenomena. This mode of interpretation applies very well to those instances in which repeated alternations of marine and fresh-water productions occur without any indications of corresponding local disturbance. (See p. 591.) As an example, we may cite the marine lacustrine formation of the Isle of Wight. (p. 674.)

The Weald of Sussex.

Application to a case proposed by Mr. Lyell.

One very obvious effect of convulsive movements, whether sudden or gradual, must always be a more rapid rate of waste, both in the land and along the coasts, than usual. It will, no doubt, be possible hereafter to draw from the *varying rate* of sedimentary aggregation in a given basin, some important evidence concerning the amount and duration of the internal movements which caused a more than ordinary accumulation of materials in the sea.

By combining with this the results of an inquiry into the local site of the convulsion, as inferred from the direction of *new sediments*, we may eventually be able to point out, with more or less probability, the original sites of these materials, and thus show how in ancient periods the wasting of one given tract of elevated rocks, has contributed materials for the accumulation of new deposits in the sea.

So long as, in the prosecution of this research, we confine ourselves to the methods of the inductive philosophy, our progress will be real though slow; new circumstances will arise to quicken the process and solidify the results, and light will gradually break in upon the yet obscure problem of the physical geography of early geological periods.

Mr. Lyell's persevering investigations into the history of the tertiary strata have produced a very remarkable attempt to determine the local origin of the materials of the English tertiaries, and the local seat of the corresponding subterranean disturbances.

The geographical relation of the anticlinal axis of Sussex and Hampshire to the tertiary deposits on either slope, has long fixed the attention of Geologists: it was proved by Dr. Buckland, that the tertiary basins of Hampshire and London were once, at least, partially connected; it was known that the first deposits above the chalk were such as to indicate prolonged action of agitated waters, that the subterranean surface of the chalk was uneven, and that among the tertiary deposits were abundance of pebbles apparently derived from water-rolled chalk flints.

Mr. Lyell supposes that "the chalk of the South-East of England, together with many subjacent rocks, may have remained undisturbed till after the commencement of the tertiary period. When at length the chalk was upheaved and exposed to the action of the waves and currents, it was rent and shattered, so that the subjacent secondary strata were exposed at the same time to denudation. The waste of these rocks, composed chiefly of sandstone and clay, supplied materials for the tertiary sands and clays, while the chalk was the source of the flinty shingle, and of the calcareous matter which we find intermixed with the London clay. The tracts now separating the basins of London and Hampshire were those which were first elevated, and which contributed by their gradual decay to the production of the newer strata. These last were accumulated in deep submarine hollows, formed probably by the subsidence of certain parts of the chalk, which sank while the adjoining tracts were rising." (*Principles of Geology*, vol. iii.)

Without following the range of ingenious arguments employed by Mr. Lyell in fortifying his hypothesis, we shall notice the facts which seem most clear in their evidence, and which can be interpreted without theoretical assumptions.

Circumstances favourable to Mr Lyell's view.

1. It is certain that the Wealden Country, with some other tracts in the South of England, has been uplifted by subterranean movements, independent of that general rise of the whole of the Eastern part of the Island before adverted to. (p. 788.) Whether this was accomplished by one or many successive movements cannot be decided by direct evidence; it would appear, however, that the convulsion was not ended till after the deposition of the whole marine tertiary series.

2. It is undoubted that the upper secondary strata disclosed in the Weald once extended much further towards the central axis, and have been exposed to enormous waste and denudation. There is nothing to negative the opinion adopted by many Geologists, that the whole of the area inclosed between the North and South Downs was once completely covered over by the chalk and the subjacent green sand system; but this admission is not really necessary to the hypothesis.

3. The tertiary basins on the Northern and Southern sides of the axis of elevation of the Weald, contain nearly the same kinds of sedimentary deposits in the same order of succession, so that both of them must certainly have been influenced by the mechanical agency of water, flowing under nearly the same conditions, from the same physical region, or from regions consisting of the same materials equally exposed to aqueous erosion.

4. The materials of the tertiary strata, in the basins of London and Hampshire, are analogous to those which have been removed by denudation of the Weald; since they consist of various coloured sands, which may be imagined to be derived from the green sands and Hastings sands, and of clays which may be supposed to have been furnished by the Gault and Weald clays, and contain pebbles which are allowed to be rolled chalk flints.

If we could venture to add to these statements, that the *order of succession* among the strata of the tertiary series was exactly that of the successive emergence of the chalk, green sands, Weald clays, and Hastings sands, the hypothesis would stand on much firmer basis than is afforded by the above favourable circumstances. After an impartial consideration of the case, we have not been able to trace such a clear dependence of the successive members of the tertiary series upon the nature of the secondary strata successively wasted, as is implied in the hypothesis, that the gradual wasting of the Weald has furnished the materials for the gradual filling up of the basins of London and Hampshire.

Chalk, the secondary stratum liable to be *first* wasted, and consequently to yield the materials of the lowest tertiaries, has furnished only a mass of flints interspersed among the variegated sands and clays, (with very little calcareous matter,) such as might claim origin from those strata of the Weald which were the *last* to undergo the influence of littoral agitation. The lower group of the Weald should have left a predominant mass of sands above the other deposits in the tertiary basins.

It may be replied, in favour of the hypothesis, that the fine particles of chalk might remain suspended, or be entirely dissolved in the water, until the period of the formation of the London clay, which is partly calcareous; that the coloured sands associated with flint pebbles were derived from the green and iron sand groups; and that the uppermost deposit of the tertiary groups may have consisted of sand which has since been removed.

Principal objection to it.

Perhaps the most formidable of this class of objections is the *total and absolute* deficiency of any of the organic remains of the Wealden rocks (except in rolled chalk flints) in any of the tertiary deposits in question. This applies especially to the tumultuous deposits of sand and shells which lie above the chalk; for here surely some of the numerous organic fossils of the green sand system, or some few fragments of the rocks, of the Hastings sands, with plants, shells, or bones, should have been found.

Some recognisable specimens of the shelly marbles of the Weald clay ought, in some one locality or other, to have been discovered in the argillaceous beds which form a predominant feature in the tertiary basins. If it be remembered, that we are here speaking of very contiguous districts; that the distance which the materials can be supposed to have been removed is only a small number of miles; and that it is matter of common observation, that by some currents or other, whether diluvial or alluvial, of transient or prolonged duration, vast quantities of organic remains, separate, or imbedded in recognisable masses of sandstone, limestone, shale, and ironstone, have been drifted fifty or one hundred miles; it must be allowed that the total absence, from the tertiary strata, in all situations yet examined, of any fragments of the Wealden rocks or fossils, is a very serious difficulty to the reception of an hypothesis which derives the one from the other.

General View of the State and Prospects of Geology.

A review of the preceding pages offers abundant proof that Geology has *escaped* from that critical stage through which all Sciences, founded on observation, must pass—the stage of speculation and dogmatism. If it has not yet arrived at the dignity which is conferred upon Inductive Science, by the establishment of very general laws, binding together a mass of dependent phenomena, it is enriched with many valuable generalizations, provided with powerful means of further investigation, and guided by distinct landmarks over a wide field of original discovery. Geology is dissociated from Cosmogony, and we are no longer made to perplex our minds with "thoughts beyond the limits of our frame," no longer required to accept an explanation of natural phenomena, founded on a violation of the laws of Nature. Leaving the impossible problem of the creation and first disposal of the matter of the Earth to those who may think there are means of solving it, but ascending beyond the short annals of the human race to the contemplation of the earlier epochs of the World, Geologists endeavour to discover the series of revolutions which have affected the Earth, by deciphering the monuments which they have successively left.

Men may be as soon reclaimed from barbarism, and raised to the summit of civilized excellence, as philosophers induced to abandon the sweet paintings of theory for the hard outlines of fact; and though in the successful career pointed out and followed by the Geological Society of London, the principle of fact before theory has been generally acted upon, it is difficult to repress the impatience which would rather mingle truth and fiction in a bold conjecture, than patiently separate the gold from the dross by the regular process of analysis. The opinion has been expressed by high authority, and seems to be gaining ground, that the time is arrived for the intervention of theory, to arrange the vast mass of facts which at present constitutes positive Geology, and to indicate the lines of further progress toward higher points of knowledge. It is, however, to be supposed, that few will obey this premature call for theory, who are aware of the many unfinished inquiries and vague generalizations which must be settled before even a prudent speculator would venture to commit himself to the tribunal of Inductive Philosophy.

State of geological theory.

We have now assembled many data for a theory; but in the very labour of collecting them, men have gradually acquired what is more valuable, a habit of limited generalization, and of continual appeal to the progress of collateral evidence in unfolding the laws which govern material nature, which at once restrains the presumption of the writer and the credulity of the reader. Under these circumstances the progress of the Science is not doubtful, and all that can be reasonably attempted toward the foundation of a theory of the Earth, is a review of the bearing of the facts already ascertained, on some of the leading problems involved in geological speculations: we shall thus learn what knowledge we have gained; what inferences it will support; how that may be augmented, and these corrected.

Lapse of Time. Geological Chronology.

All the thoughts of men are so inseparably associated with the idea of succession, that the knowledge of any physical fact is never satisfactory unless the *time* of its occurrence be given. The historical period of an occurrence is determined by reference to other events, whose place in the series of recorded human actions, or natural processes, is known. The chronology or fixing of the year in which any event took place is an admirable contrivance, the fruit of enlarged Science, which has found the means of referring all historical events to an independent and permanent natural scale, the movements in the Solar system. No person proceeds many steps in Geology, without feeling the want of some historical scale of successive phenomena, in which to interpolate new terms of the series; and though this want is to a certain degree generally, and for particular regions of the Globe perfectly, supplied by tables of the superposition of strata, we still find ourselves impelled to attempt the reduction of this historical series to the independent scale of chronology.

This difficult problem has never been fairly entered upon, except in the particular case of the diluvial and alluvial deposits. Those who admit the identity of the diluvial currents of Geologists and the Noachian flood, and suppose, with Cuvier and De Luc, that this was "the last great revolution affecting our Globe," may be expected to feel some anxiety as to the number of years which, on natural, that is to say, geological evidence, can be reasonably supposed to have elapsed since that event. In such inquiries the growth of the deltas of the Nile, the Po, and other rivers, the movement of the sands of Libya, the excavation of river-courses, may all be employed according to the views of the writer.

Superficial deposits.

Always it is to be remembered, these calculations admit as a principle the uniformity of natural superficial agencies since the diluvial period, and that period is geologically defined with more or less certainty; from such data consistent results seem attainable. There are, however, difficulties in estimating the amount of mechanical effect performed, not easily overcome. In the case of a delta, the materials may have fallen into water of unequal or unknown depth, and have been exposed to waste by currents of variable force; the movement of sands must be yet more capricious; the time employed in the recession of the falls of the Niagara from Lake Ontario to Lake Erie, has been estimated by Mr. Lyell at 10,000 years, by Mr. Fairholme at 5000; five or six thousand years is the vague conjecture, rather than conclusion, of Cuvier, of the time elapsed since the "last grand catastrophe;" and in general it must be owned that the methods of arriving at these conclusions have very little of accuracy to recommend them.

Those Geologists who admit the excavation of valleys by a force of water greater than what now passes down them, may take the date of the denudation of these as an era, and compute the time elapsed in the subsequent excavation of the river bed, in the partial or complete filling up with sediment of lakes along its course, and in the retrocession of waterfalls along the main or branch streams. Few persons, however, who value an arithmetical result for its precision, will proceed to the calculation without more information of the *rate* of these operations than is at present attained.

The fossil elephant, and other animals whose remains lie buried in gravel and other deposits called diluvial, belonged to a system of organic life, which, for some limited period prior to and during the era of those deposits, was established over a large part of the surface of the Northern hemisphere. This is termed by many Geologists the antediluvial period; some intending by this, nothing more than to mark its relation to the era of the "diluvial" currents, thus adopting the term from comparison with Scripture History. This is, properly, a terrestrial period, and we have shown the difficulty of defining its limits towards the tertiary period, which is, properly, a marine period. (p. 671.) The lacustrine tertiaries here become almost our only safe guides, and they teach us that during the tertiary period an earlier group of extinct animals, the palæotheria and their congeners, inhabited the same tracts of the Globe, as those which afterwards nourished the mammoth and mastodon. We are absolutely without any means of estimating in years the length of the interval between the era of the palæotheria buried in the Paris basin, and that of the elephants which are entombed in gravel deposits. The small extent of alluvial and lacustrine deposits of this period may perhaps justify a conjecture that it was of short duration, as compared to the postdiluvial period; but this view must not be adopted by those who attribute to the diluvial currents the excavations of valleys and other extensive alterations of the surface; because such a deluge would sweep away most of the traces of antediluvian lakes.

If the difficulties experienced in attempting to chronologize the terrestrial phenomena of the later geological periods have been sufficient to deter nearly all prudent and exact writers from venturing to give more than an illustration of the kind of reasoning to be employed, it is no wonder that for the long series of successive marine strata the attempt has been almost absolutely abandoned. It is doubtful whether we ever shall arrive at more than plausible inferences concerning the *time* elapsed in the production of the stratified rocks; yet as the consideration of this subject can be prosecuted in a strictly philosophical spirit, by the help of several satisfactory analogies, and as at all events the historical succession of the phenomena is either perfectly known or capable of becoming so, it appears an equally useful inquiry as that relating to the subsequent terrestrial periods.

Old stratified deposits.

To determine the length of years required for the deposition of all the stratified rocks under the circumstances in which they are observed, requires a knowledge of the number of repetitions of similar phenomena, and of the *rate* of their occurrence. In the Geology of stratified rocks several independent series of phenomena occur, each of which may be subjected to this examination. Of these we may notice:—

1. The mechanical deposition of sands, clays, conglomerates, &c.
2. The chemical deposition of limestones.
3. The periodical alternations of the laminæ or strata of clay, sand, limestone, &c.
4. The growth and decay of organic beings then living in the sea.
5. The successions of races of organic beings in the same parts of the Ocean.
6. The succession of convulsions.
7. The alternation of marine and fresh-water productions.
8. The alternation of marine and igneous products.
9. The metamorphism of rocks, fossils, &c.

1. Mechanical deposits of sand, clay, &c., take place only in consequence of degradation or waste of some region of the Globe, followed by a removal of the materials to some place of comparative tranquillity. Intermitting actions of this kind usually produce laminated deposits, and if the materials be of different kinds these may alternate in the sediment. In some valleys, every inundation leaves a thin layer of sediment; the number of inundations might thus be counted since any given date, and the number of years nearly ascertained. Analogous effects happen along those coasts where the tides deposit sediment; we see the same effects in many of the sandstone and clay strata which were accumulated in estuaries.

Some of the flagstones of the coal measures are composed of frequent alternations of rolled grains of felspar, quartz, and mica, which may be estimated to occupy not more than one-twentieth of an inch in thickness. Taking the thickness of the rock at 40 feet, we shall have 9600 layers, each of which marks *an interrupted action*. Let this be supposed to be the tide, allow that every tide deposited one layer, equal to about 700 per annum; this will occupy 13½ years. As far as we can ascertain, the other sandstones of the coal tract were accumulated in the same manner, though only a few of them are micaceous enough to show this minute lamination. The thickness of the Yorkshire coal measures is about 3000 feet, half of this may be considered as sandstone equal to 1500 feet, which, according to the above calculation, might be deposited in about 500 years. If we suppose the accumulation of the alternating clays to have been at the same rate, (there is good reason to admit this,) the whole period occupied in the deposition of the coal measures would be 1000 years.

Mechanical deposits.

It is perhaps unnecessary to say, that the assumption of each lamina marking the action of one tide is perfectly gratuitous, and has been adopted merely to give a specimen of the mode of calculation which must be employed if we wish to state the probable extent in years of a given geological period. Conglomerate rocks present a most convincing proof of the considerable periods which sometimes intervened between the deposition of two stratified rocks in contact and immediately succeeding one another. These rocks of turbulent origin are locally distributed, so as to be in some parts enormously thick, and in other places almost or entirely deficient. The old red sandstone conglomerate, for example, usually separates by a great thickness the greywacke slates from the superincumbent carboniferous limestone. In Herefordshire and Radnorshire, this series of red sandstones and conglomerates is many thousand feet thick, but in the greater part of the Cumbrian mountain tract it is absent, and the limestone and slate are in contact. In this case, it would be a great error to suppose the deposition of the limestone to have been immediately consequent on that of the slate. In fact, that very district gives proof that a period of violent watery tumult intervened, during which the slate rocks were broken up and rolled to pebbles, and reconsolidated into a thick conglomerate. The rate of this process can only be conjectured, by comparison with the production of pebbles by the diurnal processes of tides, rivers, and local inundations. When, as in the Rigi, we find rolled masses of conglomerate containing rolled pebbles; in the old red conglomerate of Cumberland masses of the preconsolidated slate; in the new red conglomerate of Westmoreland fragments of the mountain limestone with organic remains which have undergone *their usual chemical conversion;* enough is known to prove, to a mind not wholly blinded by false views of Science, that the monuments left for Geology to decipher carry back the History of the Earth to periods when man and his works existed only in the long foreknowledge of his Maker.

Chemical deposits.

2. Chemical deposits of limestone.—It is difficult to fix upon any method of estimating in years the time required for the deposition of a given mass of limestone. It is useless to refer to instances of the production of limestone from springs, in fresh-water lakes, in estuaries or coral reefs, unless the circumstances under which the older calcareous deposits were made are similar, a case seldom to be proved. The following process, founded on the statements in p. 551, appears the least objectionable.

It is certain that while the sandstones, shales, coals, and thin oolitic limestones of the North York moors were deposited upon the lias, a deposit almost wholly calcareous was occasioned near Bath. The whole time consumed was the same in each locality; we may therefore perhaps infer the comparative rate of deposition of the oolite and the sandstones. The total thickness of the mass in Yorkshire is about 750 feet, of which about 20 may be called limestone; of that near Bath 180 of which nearly half is sand and clay with calcareous matter interspersed. Hence we have the proportion of three feet of sandstone deposited in the same time as one of limestone.

Another instance is afforded by comparing the sections of the lower carboniferous limestone, in Derbyshire and in Tynedale. In the former tract we may take 750 feet as the thickness of limestone, with no admixture of sands or clays; in the latter, the contemporaneous strata are at least 1750 feet thick, and contain 367 feet of limestone, and 1283 feet of sands and clays, &c.; consequently, 383 of limestone correspond in time to 1283 of sands, clays, and coal, or 1 to 3.3.

3. Alternation of chemical and sedimentary deposits.—There is undoubtedly a periodicity in these alternations, but we are not yet in a state to draw any inferences, as to the cause of the recurrences, much less as to the length of their periods.

Organic remains.

4. Imbedded organic remains.—In viewing the shells distributed in rocks, we sometimes perceive, amongst a large collection of them from a given stratum, a complete series of forms from the youngest to the full grown shell; and this may be a means of calculating the lapse of time during the accumulation of a given thickness of rock more exactly than by any other. A thickness of calcareous shale, not exceeding one foot in the Yorkshire coal field, holds individuals of ammonites Listeri of every magnitude between a pin's head and an orange; it is not to be doubted that they lived where they are found; and as not one example of this species is known in any other stratum in the neighbourhood, it seems correct to admit that, during the deposition of that small mass of shale, so much time elapsed as to allow of the growth to full maturity of a long-lived cephalopode. The only other supposition which can be entertained, is that they were introduced alive by a transient irruption of the sea into a fresh-water basin, and there quickly entombed.

It is to be regretted that the age of shells has been very little inquired into among collectors. Both conchifera and mollusca are probably, in general, long-lived animals.

The immense number of shells occasionally buried in a rock is sometimes appealed to as a proof of the length of time consumed in its production; but this is a very unsatisfactory argument. Those who have witnessed the amazing increase of cyclas rivicola in the canal near Leeds, or of uniones and anodontes in many sluggish rivers near the tideway, have walked among the numerous shells on the coast of Ayrshire, or the crowds of tellinæ thrown upon the Filey sands by a single tide, will not permit to Geologists the use of such a fallacious inference. This immense abundance of fossils is often a local phenomenon in the rock, and one which, when better understood, will aid materially our conceptions of the agencies which were concerned in its accumulation.

The nearly vertical position of certain fossil plants, a phenomenon by no means rare among sandstone rocks, affords good ground for caution in assigning very great extension of years to geological periods. The stems of equiséta in sandstone of the oolitic era, (page 625,) of sigillaria in sandstone of the coal series, (page 596,) of dicotyledonous wood in limestone of the Isle of Purbeck, seem to teach us in plain terms that the accumulation of these rocks was not of that slow and insensible kind which is often attributed to them. Whether we suppose them to be in their place of growth, or to have been swept down to their present situations by land floods, the result as to our present argument is the same; the accumulation of transported sediment must have been so rapid as to prevent the decomposition of the cortical portions of the plants, the wearing away of the superficial structure, or the bending of the stem beneath currents of water. No one doubts that the bed of stone three feet thick, which encloses equisetum columnare at High Whitby, was laid by a single inundation; we will suppose it an annual occurrence; the other sandstones and shales of this series must have the same rate of origin ascribed to them; this would give for the formation of the oolitic sandstones and shales in the North York moors a period of 150 years. About the same, or a slower rate of formation, may be supposed for the case of sigillaria in the coal sandstones of Yorkshire; for these stems, when above two or three feet long and nearly vertical, pass through more than one, sometimes four or five beds of stone. (Altofts near Wakefield.)

Succession of races.

5. Successions of races of organic beings in the same parts of the Ocean.—The succession of different races of organic beings in the same parts of the Ocean, is one of the leading facts which speak the most impressive, though not the most exact, language on the subject of the long duration of geological periods. For, whether we consider those cases in which the extinction of old and the introduction of new species was gradual, or others when the changes were sudden and complete, nothing that we know of the actual constitution of Nature will justify us in admitting that these revolutions in the animal world followed quickly one after another. We are impelled to conclude that, for the existence of any given race, consisting of thousands of individuals of many hundred species, imbedded in many different kinds of rock, in distinguishable groups according to their habits of life, a long time must be allowed, or else the whole constitution of Nature was in a state of forced acceleration, so that the work of ages was crowded into years. Whether we suppose that new species were contemporaneously created in all the situations where they lived and died, or distributed from one local origin over the sea, or transported by currents from other oceanic centres of life, no one who considers the stability of the actual system of watery life, will be easily persuaded to believe that these prodigious changes were operated over a large part of the Globe in times that can be included within such narrow limits as those of human experience. Yet who will venture to translate the vague and almost poetical visions of long duration, which the contemplation of many repetitions of these local revivals of Nature so powerfully awakens, into the language of chronology? It is evident that the day is not yet arrived, or rather it is gone by, for dogmatizing about the antiquity of the crust of the Globe.

6. The successions of convulsions in the same physical region may be very properly mentioned as a vague indication of the lengths of geological periods; but cannot at present be employed in a more exact manner to determine their duration.

7. The alternation of marine and fresh-water products is another of those grand phenomena, which, whether rightly or not, is sure to make a deep impression on the mind; though the rarity of the case, and our ignorance of the principal efficient circumstances, must wholly exclude it from among the data for accurate calculation of geological time.

8. The same may be said of the alternation of aqueous and igneous products.

9. The metamorphism of rocks, &c., in consequence of the local or general effect of heat, may possibly one day be sufficiently understood to permit some attempt towards determining the intensity and rate of the communication of heat, and thus more or less directly bear upon the question of time. The chemical changes of organic remains are evidently less related to time than to other circumstances, such as, the original nature of the body, the sort of substance in which it is imbedded, and proximity to sources of mineral impregnation, whether by aqueous or igneous solution, or electrical transfer of solid ingredients.

Successive Conditions of the Globe.

The object of geological researches has been till lately very little understood by those not directly conversant with the subject; and even professed Geologists do not always restrict their inquiries within just bounds. It is difficult for a speculator to believe that Geology may become a very important branch of natural Science, though it should wholly disclaim the investigation of problems concerning the creation or concentration of the matter of the Globe, or the establishment of the laws of the universe. To know the successive changes which the Globe has undergone, and thus to trace a retrospective outline of its successive conditions, is actually attempted by Geology; but the very processes employed in this enterprise are founded upon the recognition of the existing laws of Nature, and altogether exclude the popular notion of a chaos, and the philosophical hypothesis of a solid Globe condensing from an atmospheric expansion.

Undoubtedly the progress of legitimate Geology teaches us that the same laws of Nature have operated on this Globe under very different circumstances, as to temperature, relation of land and sea, animal and vegetable life, and many other things; and it is become a proper problem for Geology to discover these circumstances. In this point of view, the reflections of Leibnitz, and the mathematical labours of Laplace and the astronomers, become of great value, since they help to fix conspicuous landmarks for the guidance of the surveyors in this large field of Science; but let no one delude himself with the notion of discovering, by geological processes, the emerging of the harmoniously adjusted terraqueous Globe from a former state of chaos. It is certainly not a philosophical, and surely cannot be thought a religious notion, that man shall ever discover among the works of God, the traces of a period when his divine attributes were first awakened to rescue his creation from anarchy. Geology takes for granted the existence and collection of the matter of the Globe, with its supernatant Ocean, and its enveloping atmosphere. Except in the degree of influence which circumstances permit them to exert, it takes for granted the uniformity of action of all material causes. The investigation of miracles can never be admitted into natural Science.

The dimensions of the Globe have remained constant since the days of Hipparchus; (born 160 B.C.) for Laplace has shown that the length of the day has not sensibly varied since that time, which must have happened if the diameter had perceptibly changed: if the Globe had contracted, the diurnal period would have been shortened, and *vice versâ*.

This is usually considered a very formidable argument against the doctrine of internal heat, and its corollary, secular refrigeration and contraction, to which theorists have very freely resorted, as the prolific source of all subterranean movements, changes of superficial temperature, elevation of continents, volcanic eruptions, injection of igneous rocks, mineral veins, &c. Fourier's researches, however, into the mathematical theory of heat, show that, under the conditions of sensible constancy of dimension, and variation of superficial temperature according to solar influence, we are at liberty to suppose the existence of deep seated heat of any intensity, provided there be direct indications of corresponding augmentation of sensible temperature below a certain depth. Such indications, it is very generally allowed, are presented by the observations in mines and collieries in Europe, Asia, and America.

Secular refrigeration.

With regard to secular refrigeration, the experience of two thousand years undoubtedly shews that its effect in contracting the Earth's diameter has been for that period insensible; but, first, it must be observed, that the hypothesis supposes the effect of refrigeration to be a contraction of an internal nucleus, and a consequent separation between it and the solid crust, which continually increases until the crust is broken by a *convulsive collapse*; secondly, it is sufficiently evident that, by the accumulation of nonconducting materials over a source of heat, the diminution of this heat must become continually more and more slow, so as at last to be insensible even in very long periods. If, then, it should appear that the leading phenomena of the ancient History of the Earth can be well explained by help of these suppositions, there is nothing in the mathematical theory to prevent their provisional adoption, on the basis, not unfrequently employed in Natural Philosophy, that they serve to explain many phenomena.

Volcanic action.

It is by no means necessary to couple with the hypothesis of internal heat, the doctrine that volcanic action arises from this cause only: the various chemical characteristics of volcanic action must be examined upon their own evidence; and it does not appear that the theory of volcanic operations, advocated in a former part of the Essay, is at all deprived of its applicability, or rendered superfluous, by admitting the existence of intense internal heat. On the contrary, under the influence of a high temperature, the admission of oxygen and water would still produce upon the fluid metalloids and metals the effects usually ascribed to such a cause, and perhaps more easily than if they were solid, and the results would still be proportioned to the circumstances of the locality.

These remarks are not introduced for the purpose of advocating the hypothesis in question, but to rescue those who have adopted it, and by it endeavoured to illuminate some of the darkest pages of Geology, from the imputation of invoking causes which chemical and mathematical researches concurred in disproving.

Displacement of the Earth's axis.

The moderation which Geologists were so slow to learn, has prevented them from reviving the ancient speculation which ascribed the leading phenomena of Geology to an extensive shifting of the Earth's axis, and consequent displacement of the Ocean. To be consistent, we must suppose this mighty operation to have been many times repeated before the occurrence of the Deluge which it was invented to explain. Perhaps the *probability* that every part of the Globe *equally* requires this displacement of the axis, but requires it in *different directions at the same time*, may be sufficient to prevent its resuscitation. It is too much, however, to treat it as an absurdity, merely upon the ground that the shells of equal density within the Globe have their axes, at the present moment, nearly coincident with those of the surface; for Sir J. Herschel has expressed the opinion that the spheroidal figure of the Earth might be acquired during rotation though its parts were not fluid.

But, as Mr. Greenough has observed, "be the cause what it may, the fact is certain, that the temperature of the crust of the Earth was higher when the coal measures were deposited than now, and we have reason to think it was still higher at antecedent periods. That a considerable degree of heat still exists, either partially or generally, at no great distance from the surface, appears from thermal springs and volcanoes." (*Geological Society's Proceedings*, 1834.)

Origin of terrestrial organic life.

In accordance with this view is the common opinion, that geological inquiries have discovered traces of a period in the History of the Globe, when neither animal nor vegetable life was established upon it. This opinion, ably expressed by Dr. Buckland in his *Vindiciæ Geologicæ*, is chiefly supported by the facts observed in studying the primary and transition strata. The view of the subject which is most consonant to the course of inferences adopted in this Treatise, has been already sufficiently expressed in the review of the primary strata, (p. 570, 571.)

Whatever may be truth on this point, it is certain that the successive systems of organic life, both terrestrial and aquatic, animal and vegetable, show the same general principles and relations as that to which we belong. Geology has disclosed various and remarkable animals, not paralleled in existing nature, and plants of singular forms, but nothing which deviates from those general laws of structure and function which govern the actual organic creation. The plants and animals of different geological periods do not differ more from one another, than those in opposite climates, or even distant localities at present. There is even to be observed among the several successive systems of organic remains some real analogy to existing local Faunas and Floras: the oolitic fossils have, perhaps, a greater resemblance, for instance, to the living productions of Australia and the Indian Islands, than to those of any other situation; while the plants and uniones of the Northern English coal tracts remind us of the physical characters of the American continent rivers and islands.

Periods of convulsion and repose.

There is, perhaps, no point of theoretical Geology more certainly established than that, in any given small area of the surface of the Globe, long periods of ordinary action of natural causes have been several times interrupted by epochs of extraordinary disturbance; that the relation of the level of sea and land has remained for a long time the same, or very gradually changed, and afterwards been altered by internal convulsions. It is also admitted that this law has an extensive though then less exact application; that the periods of ordinary and crises of extraordinary action were respectively contemporaneous over very large regions of the Globe, and even with respect to some of the cases admit of general application. It appears, also, that the nature of the strata deposited differs more or less according to the several successive periods, and that the races of organic remains, in several important cases, are subject to contemporaneous crises. On this evidence, joined to some theoretical considerations, is founded the modern admission of the doctrine of alternating periods of convulsion and repose; a doctrine which was held by ancient Philosophers, revived by Leibnitz and Hutton, and illustrated by Cuvier and De Beaumont. Perhaps this view of the subject was never more clearly expressed than by Leibnitz, whose just sense of the philosophy of Geology has been lately placed in a strong light by Mr. Conybeare. His view is, that the powerful agencies exerted in displacing and altering the solid crust which gradually thickened over the ignited nucleus, have many times renewed the face of the young Globe by the eruption of concreted igneous rocks from below, and the deposition of stratified rocks by water above; and that the Globe was, by these processes, more and more diversified with mountains and valleys, and subjected to various physical conditions; *donec quiescentibus causis, atque æquilibratis, consistentior emergeret rerum status.*

Uniformity of natural agencies.

Mr. Lyell's pictures of the successive conditions of the Globe are all drawn to one scale, from the unvarying standard of its present state; his hypothesis admits local alternations of ordinary and critical action, but denies any thing like a general paroxysmal effort of natural agents; nor is there, between the ordinary and critical stages of his processes, any conspicuous difference. The principle of his system is, that the disturbing internal forces exert themselves in irregular succession beneath all the points of the surface of the Gobe; and that the ordinary chemical and mechanical agencies of Nature are thus modified in their intensity, and diversified in their effects, and applied to produce an endless series of destructions and renovations, which, upon the whole, compensate one another continually.

In this system, the postulate required is *unlimited duration;* in the other, a varying momentum of natural agencies according to *difference of condition:* the one is a system of continual, the other of intermittent compensation. Nature offers to our view examples of both these cases, and on a large scale; it is therefore very unwise to assume one or the other on account of our notion of its greater probability; we must see which of the systems finds support from the facts of the case. It has been already seen that our *proofs* of the periods of time elapsed are neither clear, satisfactory, nor complete; much of the evidence on this subject is in unknown terms; but estimates derived from probable views of the mechanical composition and organic contents of the strata, do not appear to warrant the postulate of unlimited duration. (See p. 795, 796.)

On the contrary, be the duration of geological periods what they may, it is clear that the Earth has successively undergone great physical changes; terrestrial agencies must therefore have operated upon it with a corresponding variation of effect; one of these changes of condition, that of superficial temperature, is not explicable by any of the known periodical inequalities of the Solar system, but seems in harmony with the general theory of internal heat, gradually becoming less and less sensible as the external crust thickened, and the surface of the Globe approached to a state of equilibrium.

Successive Conditions of the Materials of the Crust of the Globe.

The question of the origin or first condition of the elementary ingredients of earthy and metallic substances, if capable of solution, must be referred to another Science; but inquiries into the successive conditions of the mineral substances which appear in the crust of the Globe, is one which, in some shape or other, must be often proposed to a Geologist. It is difficult to stop at the recognition of the igneous origin of some rocks, the aqueous production of others; we cannot avoid examining, whether any evidence can be found for determining a prior condition of the substances contained in these rocks. Facts of great importance here come before us; we see examples of new rocks produced by heat from aqueous deposits, and sedimentary aggregates of the disintegrated ingredients of volcanic and plutonic masses. The deposition of limestone offers very remarkable variations, and it is impossible to consider the composition of the minerals in crystallized rocks, without feeling that the resources of Chemistry are or may become capable of advancing us one more step in the analysis of the series of conditions through which the solid ingredients of the Globe have passed.

The time is not long gone by when Werner, who, with far less moderation than Dr. Hutton, wished to begin at the beginning, could find thousands of followers in the startling dogma, that all the rocks observed near the surface of the Earth, were deposited from one chaotic fluid, which first permitted the crystallization of granitic and other rocks, and afterwards produced the secondary sandstones, shales, and limestones. It is possible that even yet there may be persons who can believe that these secondary sandstones were produced by a chemical decomposition of the ancient Ocean; which, to answer all the unreasonable demands upon its powers, must have been endowed with more than the creative energy of a Brahmà, and capable of surmounting every chemical and mechanical impossibility—of crystallizing into sand, condensing into limestone, and subliming into metal!

Leibnitz, and a large portion of modern Geologists, also attempt to fix something like a beginning to their system, a point of geological time when the change from a fluid to a solidified surface permitted the developement of that series of intermitting igneous and aqueous actions, which has brought the Globe by many revolutions to its present state of comparative repose. The followers of Dr. Hutton see no such commencement to their series of terraqueous effects; they find no physical traces of a beginning, nor any change of operation which should give the prospect of an end of this series of effects proportioned to the time elapsed. Yet, as one hypothesis admits locally, periodically, and repeatedly, what the other supposes to have happened generally and in one succession, there is no necessary disagreement in the interpretation of particular cases. This is not always remembered by those who engage in the controversy concerning the uniformity of natural effects.

Successive conditions of certain substances.

If we trace back the history of the materials of the sedimentary sands and clays now in process of formation at the mouths of rivers, along the sea-coasts, and in other situations, we shall find that these materials are often derived from ancient superficial deposits left by local or extensive floods; examination proves that the materials of these deposits were often obtained by the violent breaking up and attrition of far more ancient previously solidified strata; in several instances it is manifest that these are nothing else than the oceanic accumulations derived from disintegrated primary strata, or of disintegrated pyrogenous rocks.

As an example, we shall quote a well-ascertained series of facts, which leave no doubt of the many changes of condition through which the granular ingredients of modern sedimentary deposits have passed. 1. The Ouse, Trent, and other great rivers connected with the Humber, are so filled with the finer parts of the sediments which fall into the sea along the wasting cliffs of Holderness, that their flood-waters, when introduced to the lower ground along their banks, deposit a great thickness of valuable soil. The sandy and coarser parts of the sediment are collected in various irregular positions in the Humber and along the coast, and the pebbles remain on the beach, or follow its descent for a small distance into the sea. 2. The diluvial cliffs, which by their destruction afford this rich supply of fertile warp and sterile sand, contain fragments of all the rocks in North-Western Yorkshire, that is to say, basalt, limestone of many kinds, cherts, sandstones, fine-grained and coarse-grained millstone grit, shales, ironstones, and coal; fragments of granite, hypersthene rock, and greywacke slates from Cumbria; all imbedded in a vast thickness of sands and clays composed of the same comminuted materials. 3. The millstone grit, fragments of which occur in this diluvial mass, is a compound of felspar, quartz, and mica, with occasional admixtures of other substances. These minerals are easily recognised as *rolled and water-worn masses*, derived from porphyritic granite, gneiss, and other such rocks. The felspar is always perfectly crystallized within, but the external surface is water-worn; the mica has lost its angles; and the quartz fragments are only in the state of large grained sand. Plainer proof of mechanical aggregation of ingredients which once composed a crystalline felspathic rock, cannot be desired; many such instances are known, and the inference is generally allowed.

Extension of this inference.

As far as the results of a careful examination of ordinary sandstones can be trusted, there is no reason to refuse to them, as a general rule, the same kind of origin as to coarse millstone grit. Most of them have the same ingredients, though it frequently happens that the felspar is in a state of decomposition. Shales and clays are to sandstones what the fine warp in the water of the Humber is to the sands in its channel; we may then venture, in a moderate spirit of generalization, to assume, that sedimentary sandstones and shales have originated in the mechanical action of water upon the disintegrated granular ingredients of pyrogenous rocks.

Any one who has sufficiently observed the varieties of sandstones and shales on the one hand, and of stratified primary rocks on the other, and considered the nature and amount of the changes produced upon them respectively by heat; or properly weighed the observations and reasonings of Macculloch; will have no difficulty in admitting the views as to the origin of the latter class of strata advocated in former parts of this Essay. We are therefore conducted, apparently by a legitimate process of induction, to the conclusion that all the stratified rocks, limestone and some particular strata excepted, are derived primarily from the decomposing agencies of Nature operating upon pyrogenous rocks; and we thus find a natural limit to the series of conditions through which these materials have passed. This conclusion, though perhaps less distinctly stated, is essentially recognised in modern geological systems and is *felt* to be substantially true, though it still leaves many things to be explained.

An inquiry as to the origin of the vast masses of stratified limestone, is a subject of considerable difficulty. In a great majority of instances the limestone formed at the present day is the result of chemical forces, and the same was probably the case in earlier periods. In particular instances, calcareous deposits have partially or wholly a mechanical origin; as when a stream brings down the waste of a chalky or oolitic district, and deposits the sediment in a lake; or when the currents of the Ocean drift shells and other marine exuviæ and lodge them in the midst of coral reefs. Observers of the growth of coral islands have detected several facts as to the intermixture of decomposed fragmentary and entire calcareous marine exuviæ with coral rock, which seem to render not improbable the opinion of Geologists, that some of the older secondary and transition limestones are in places only magnificent coral reefs.

Origin of limestone.

Perhaps nowhere has the mechanical origin of limestone been assumed to a greater extent than in the Huttonian system of Geology; for it seems to be an essential part of that system, that the stratified limestones are nothing else than triturated shells and other calcareous exuviæ. By those who adopt this view, chalk, the least compacted kind of limestone, is usually taken as an example. It is sometimes difficult to avoid imagining that the powdery magnesian limestone is a recomposed rock, derived from the ruins of magnesian beds of carboniferous limestone. But this cannot be a true account of the matter; for, 1. there ought to be far *less magnesia* in the compound. 2. This is in some instances an atomic combination of carbonate of magnesia and carbonate of lime. 3. This limestone is often really a granularly crystalline-rock, (like the older magnesiferous beds of mountain limestone,) and seldom appears to justify the least suspicion of the mechanical agency of water.

But nothing is more certain than that of all the strata yet discovered, limestone is exactly that which, by the regularity and continuity of its beds, by the extreme perfection of its organic contents, and by the absence of proofs of mechanical action, gives most completely the notion of a chemical precipitate. It appears sufficiently probable, in several instances, that the quantity of limestone deposited in a given geological period was least towards the shores, and greatest towards the deep sea; exactly the reverse of what happens with the mechanical deposits of sandstone and shale; it may therefore be viewed as an oceanic deposit, resulting from a decomposition of sea water, aided in many instances to a wonderful extent by the vital products of zoophytic, echinodermatous, and molluscous animals. According to this view, it is easy to understand the repeated production of limestones of the same mineral character at different periods; nor need we feel surprised that, occasionally, limestones of the same age differ in properties.

However, all these views end at last in one, *viz.* that the earliest condition which we can assign to the carbonate of lime, is that of extrication from some solution of lime in water, by chemical or vital processes. And here, perhaps, it will be wisdom to pause, for though some have ventured to imagine that the lime might be derived from the decomposition of particular ingredients in primary igneous rocks, and others may suppose that the Ocean would more directly obtain this with other ingredients from the oxidized fluid nucleus of the Globe, such speculations are beyond the pale of Inductive Geology, and involve too many hazardous assumptions to be at present worthy of the notice of other Sciences.

General result.

The general tendency of geological reasoning is to establish the inference, that a large portion of the stratified deposits have been formed from the wasted ingredients of pyrogenous rocks: all the phenomena of volcanoes and ancient igneous eruptions prove that *locally* stratified deposits are reconvertible to crystalline rocks by the force of heat, and very *generally* alterable in character so as to approximate to the actual products of heat. Mr. Lyell puts this to the extreme, and supposes that the calorific energy of the interior of the Earth is constantly acting, so as to reconvert sedimentary into crystalline aggregates, *equal quantities* in *equal times*, and thus to maintain a perpetual equilibrium between the liquefying internal and the solidifying external agencies of the Globe. This speculation is much too poetical to be examined according to the dry rules of the Baconian Philosophy: if the heat expended in this operation be obtained from chemical processes, these must gradually tend towards equilibrium; if from a general internal reservoir of caloric, that reservoir must become less and less prompt in supplying the incessant demand: either of these effects operating through *indefinite time* must cause the gradual refrigeration of the surface of the Globe, a consequence not favourable to the hypothesis of the uniformity and continual compensation of the effects of internal and external terrestrial agencies.

GEOLOGICAL MAP OF EUROPE

from various authorities by

John Phillips. F.G.S.

INDEX TO GEOLOGY.

To facilitate the study of the Article Geology, and to make known the nature and the views advanced in it, is the object of the following abstract. The subjects discussed in Geological Treatises of modern date are, of necessity, extremely varied, for the Natural History of the Earth is too vast and diversified a problem not to require continual reference to the truths of collateral Science. In the present Treatise, a great portion of the inferences and general reasoning is, indeed, collected into a separate and final chapter; yet, in many instances, the inferences from phenomena are introduced after the description of these, especially when it seemed likely to render the succeeding descriptions more clear. The following summary will explain the distribution of subjects throughout the four Chapters of the Treatise, and serve as a General Index, permitting, at the same time, a connected view of the Science.

CHAPTER I.

PROGRESS AND PRINCIPLES OF THE SCIENCE.

Progress of the Science.

Page

529 *Definition*, with reasons for its wide limits.

Speculative Geology gradually changing, with the progress of Physical Science, into

530 *Inductive Geology*, which, in different Countries, was based on different data. *Lister* originated the *agricultural school of Geology*, which has nowhere made progress commensurate with its importance.

Mining knowledge was the basis of another school brought to eminence in Germany under the auspices of Werner, who claims the merit of introducing, more clearly than had been done before, the consideration of relative time and succession of phenomena.—Of this

531 *Werner's series of formations* is a remarkable monument.

Mitchell, *Whitehurst*, and *Saussure* have distinct claims to praise, the former for comprehensive views, the latter for diligent researches.

532 *Inductive Geology* was, however, principally founded on a *knowledge of organic remains.* Rude admiration of these monuments of earlier Nature animated, nearly at the same time, the Naturalists of Italy, France, and England; and the discussions respecting their origin led to the introduction of Zoology and Botany as auxiliary Sciences to Geology: and in Mr. Smith's hands to

533 *A correct classification* of stratified rocks, and the important discovery of the relation of *systems of organic life* to definite geological periods.

534 *Hypotheses* are thus devoted to oblivion, and *the modern cultivators of Geology*, aware of the grand problem committed to their industry, labour assiduously, and labour together, in the patient interpretation of Nature.

Materials in the Earth.

The mean density of the Earth, as known by astronomical and mechanical discoveries, combined with other knowledge, leads to three probable deductions as to the *interior* of the Planet, which are stated, and which are of great importance in limiting the range of geological speculation.

535 *The earthy compounds of the exterior* of our Planet, as known by observation, are referred to certain groups according to their chemical constitution.

Stratification.

536 *The regular arrangement of rocks on the surface* is shown to depend on a *regular internal arrangement* called stratification; such that the "strata are arranged, with respect to one

537 another, in a constant order of succession." From this *superposition of strata*, with according *declinations*, and considerable extent or *continuity*, it follows, that *stratification* is a fundamental condition of many rocks, and that the Earth is externally of a lamellar structure, the layers marking particular periods of its formation.

Page

Distinction of Stratified and Unstratified Rocks.

537 *From the relative situation* of these two classes of rocks,

538 *The distinction* of their mineral characters, and mode of aggregation, and *their contents*, a conclusion is drawn that they were the results of different agencies, the former deposited from *water*, the latter produced by *heat*.

538 The division of geological study into two branches is thus indicated, and the sections of the Treatise which follow are made to correspond.

On Stratification in general.

538 *Strata:* the definition of Professor Playfair limited; *interposed* strata are described; the *thickness* and *lamination, parallel* or *oblique*, are noticed; and certain *collective terms* employed by Geologists explained.

539 *The series of British strata* is then presented in a tabular form, under the divisions of tertiary, secondary, and primary strata, according to the several *formations* and stratified groups.

Disturbed Stratification.

540 *Cuvier's fundamental principle* for investigation of disturbances of strata applied to cases of *vertical strata* and *contorted beds.* (See pl. i. fig. 4.)

541 *Faults*, or the lines of fracture of disturbed strata, considered with reference to a certain law of direction, (also applied to several mineral veins and dykes,) and to their relative antiquity; *principal epochs* of convulsion ascertained by this process of reasoning, and the leading physical features of the Earth's surface shown to be dependent on subterranean movements.

542 *These movements, and the disruptions of* strata which they have occasioned, are shown to be a part of the general plan of terrestrial creation, affording that variety of surface and conditions to which organic life is known to be adapted, and causing the exposure, under varied circumstances, for the use of man, of all the minerals and other useful products near the surface of the Earth. (See pl. i. fig. 5, 6, 7, 8.)

Internal Structure of Rocks.

543 *Joints in different rocks* possess peculiar characters, and communicate to them distinctive features, independent of their other structural peculiarities.

The general cause of joints and fissures admitted to be contraction of the mass after partial consolidation; some general agency, like that of electricity, appealed to for the production of the symmetry and constant direction of joints in large districts; and *local changes of internal structure* referred to the application of long-continued heat. (See pl. i. fig. 9.)

Mineral Composition of Strata.

544 *Both mechanically transported sediments* and *chemical precipitates* are recognised among the stratified rocks, *the whole series* of which consists of alternate layers of several calcareous, arenaceous, argillaceous, ferruginous, and carbonaceous compounds.

545 *The phenomenon of alternation* must be distinguished from that of *gradation* of beds, though both aid to produce what is called a transition of terms in the stratified masses. (See pl. i. fig. 10, 11.)

The proportions of chemical and mechanical deposits vary in the different systems, and give occasion to some general reflections as to the causes concerned.

Condition of Organic Remains.

546 *What tribes* of living beings are recognisable in the fossil state;

What portions of the original structure are preserved;

In what condition they were imbedded; entire, disjoined, fragmented, or worn; these questions having been answered,

547 *Subsequent changes* of composition may be investigated,

In plants, corals, shells, &c., and the effects discovered may be compared with *analogous modern* processes, and referred to the original nature of the bodies and to the peculiar influences to which they were subjected in different rocks.

Page

Distribution of Organic Remains.

549, 550. *The relative number* of fossil and living species of plants and animals is first touched upon; the proportions analyzed with reference to the original nature of the bodies; and a comparison instituted of British recent and fossil species of zoophyta, conchifera, gasteropoda, cephalopoda.

550 *The European fossil species* are next tabulated.

The distribution of organic remains in the Earth is next considered with reference to the *number* of them in different rocks; the Table given suggests remarkable inferences; *the relation of kind* between recent and fossil tribes being considered, and the *relations* of the *fossils of different strata* to one another, it follows, that each stratum was successively the bed of the sea, and that *successive systems of strata* enclose *successive races of animals and plants.*

551 These being of *terrestrial* and *marine origin* give us, in some degree, the history of both the land and the sea; marine races indicate the oceanic origin of limestone; terrestrial plants mark the transport of the materials of arenaceous rocks by rivers and inundations from the land; and thus, the first approximations arise toward the determination of the boundaries of the ancient oceans.

552 *Marine exuviæ* being considered, it is found that rocks of similar chemical quality have some resemblance in certain tribes of fossils; (zoophyta;) but more important is the fact, that they are associated according to the *periods of their existence*; so that

Strata of different age contain, for the most part, different fossils.

Strata of the same age contain, even over large tracts, some identical and many similar fossils, according to the doctrine of Mr. Smith.

553 *Repeated changes in the races* of organic beings, by which they have been, at different geological epochs, successively brought nearer and nearer to the forms of existing nature, are thus established.

M. Deshayes' results in this inquiry, derived from tertiary strata, are stated, and the *identification of strata by characteristic organic remains* is considered, and the change of organic remains put in connection with the corresponding change of mineral composition of rocks.

554 *Terrestrial* exuviæ are shortly examined with reference to the same principles.

CHAPTER II.

DESCRIPTION OF THE SERIES OF AQUEOUS DEPOSITS WITH THEIR IMBEDDED ORGANIC REMAINS.

554 *The history of the successive systems* of rocks, deposited from water, is preceded by a discussion of what forms their general floor or basis. It being admitted that granite and other unstratified rocks, (see p. 537,) originating from the action of heat, form this general floor. The "primary strata" are considered with reference to the hypothesis of

555 *Metamorphism* of rocks of all ages, and the conjecture that earlier strata than those called primary may have been absorbed into the melted nucleus of the Globe. Certain conclusions are stated; a grouping of the strata into systems follows, and these are described according to the eras of their production.

PRIMARY STRATA.

557 *The primary strata* are treated of as forming the skeleton and framework of the Earth's surface, ranging along the mountain chains and groups, and encircling and dividing the great European, Asiatic, and other basins.

Gneiss and Mica Slate System.

558 *Principal rocks described;* the order of their succession examined; the origin of *gneiss;* its stratification; the minerals which it contains; the rocks associated with it; and the transitions from this to other rocks noticed.

550 Similar review of *mica schist, quartz rock,* and *primary* limestone.

560 *The districts* occupied by the gneiss and mica schist systems are next described; Cornwall, Wales, Cumberland, Scotland, (pl. i. fig. 12.) North of Ireland, South of Ireland, Brittany, Pyrenees, Central France, America.

Page

Slate System.

565 Relation of this to the preceding system; (pl. i. fig. 13;) the Cumbrian slate region taken as a type; dark lowest slates; red rock, middle green slates; dark fossiliferous limestone; upper slates also fossiliferous.

567 *Cleavage* of slate; slates of Scotland, Ireland, Isle of Man, Wales, (from Sedgwick,) Anglesea, (from Henslow,) the groups in the grauwacke series of Wales, established by Murchison; slates of Charnwood forest, Cornwall, and Devon, Brittany, Pyrenees, Ardennes, Rhine Valley, Harz, Scandinavia, Tarentaise, North America.

569 "*Transition*" *limestone* shown to be analogous, in some respects, both to the primary and carboniferous limestones, but distinct from both. As a general truth, it is concluded that the whole series of strata forms but one great locally interrupted series.

570 The succession of the *whole British primary series* presented in a tabular form.

General Conclusions concerning Primary Strata

570 Are next presented under the following heads, affirmatively:

General basis of igneous rocks.

Influence of heat on primary strata.

Organic remains absent from the lower primary strata, but frequent in the upper.

Objections to the conclusion of greater manifestations of igneous agency in the older periods, considered.

Disturbances of the Primary Strata.

571 *The effects of convulsions* which happened

During the accumulation of the slates, and after the deposit of the slates, considered, with reference to the mean direction of subsequent strata; exhibition of plutonic rocks, mineral veins, &c.

Organic Remains of the Slate System.

572 Plants, polyparia; 574, radiaria, conchifera; 578, gasteropoda; 580, annulosa, crustacea. Remarks follow each class of fossils, and a summary is given, 581; (the suggestion regarding the fossils of the South of Ireland, 577, 580, has been admitted by Mr. Weaver to be correct; M. De La Beche has no doubt that the limestones of Devonshire do belong to the transition epoch.)

SECONDARY STRATA.

Carboniferous System.

581 *New physical geography* of the Globe at the commencement of the carboniferous period; produced by the convulsions treated of, 571.

Divisions of the carboniferous system:

582 *Old red sandstone formation,* origin from local convulsive movements; its characters in the Cumbrian tract, Wales, Monmouthshire, &c., Scotland, Ireland.

584 *Mountain or carboniferous limestone formation;* geographical extent, and modifications of the formation, illustrated by original investigations in the North of England. The several groups of the formation described, as to composition, physical geography, &c., *viz., scar limestone, flagstone series, upper limestone belt, millstone grit.* The mechanical origin of this latter series discussed.

589 *The coal formation; its composition* compared to that of the mountain limestone series.

Range and extent of the coal formation; *English coal* fields compared in districts.

The Yorkshire coal field described as a type; lower, middle, and upper series; 592, the great Northern coal fields, great South Wales coal field; 593, Forest of Dean, Somerset, &c., Flint, plain of Shrewsbury, Coalbrook Dale; 594, Clee hills, the central coal fields, Irish coal.

594 *General view of circumstances under* which the coal beds were deposited.

1. Its origin from vegetables proved; (see also 547;) 2. these plants grew on land; 3 the analogy of coal beds to buried peat bogs, subterranean forests, &c., to lake and river deposits, investigated; 596, effects of the higher temperature existing in former times upon the Globe upon the growth and inhumation of plants; conclusion adopted as most generally applicable, that the plants were swept down from the land to lakes and estuaries of the sea; exemplifications of the process.

Page

Convulsive Movements of the Carboniferous System

597 Of very general extent: 598, the Penine chain uplifted; the coal fields of Lancashire and Yorkshire divided; other elevations; the Forest of Dean, the Ardennes, &c.; relation of convulsive movements to mineral veins, &c.; observations on these.

Organic Remains of the Carboniferous System.

The extensive catalogues which are given are accompanied by sufficient explanations.

599 Plants. (Polyporites Bowmanni of Lindley is a fish scale. It occurs in several other localities.)

603 Analogy of fossil and recent plants; conclusions on this subject.

603 Polyparia; 604, radiaria, conchifera; 606, mollusca; 608, general summary.

Saliferous System.

608 *General view* of the composition, subdivision, and range of this system in England; 610, remarks on certain members of the saliferous system in England; marl slates; yellow magnesian limestone; 611, laminated limestone; rock salt of Cheshire described; 612, the saliferous system of Europe; organic remains; sections in the Vosges, North-East of Germany, &c., compared with that of the North of England; remarks on salt.

614 *Circumstances attending the origin* of the *saliferous system;* arguments for its marine origin; local absence of organic remains; prevalence of certain colours; prevalence of magnesia; difficulties with respect to the *origin of the salt and gypsum.*

Organic Remains of the Saliferous System.

615 Plants, polyparia; 616, radiaria, annulosa, conchifera; 617, gasteropoda; 618, cephalopoda, crustacea, vertebralia; 619, summary.

Disturbances of the Saliferous System.

619 In England, only slight and few; in the Vosges, Brittany, La Vendée, Morvan, Böhmerwald, Thuringerwald, Avallon, Autun.

Oolitic System.

619 Its conformity to the saliferous system in position; differences in mineral character and organic remains, the phenomenon of alternation at the base and top of the system; composition in different Countries of Europe.

620 *Classification of the English series* in a tabular form.

Range of the lias; its general characters, geographical, mineral, organic; 621, the lias formation of Yorkshire and Lincolnshire subdivided and described; lias of the Midland Counties; 622, of the Cottswold, of Bath and Dorsetshire, of North Britain, South Wales; lias of Autun, Chalons, Luxemburg, Wurtemberg, Banz; remarkable characters of lias in Swisserland.

623 *The lower oolite formation;* its range, geography, elevation, escarpments; type of this formation at Bath described; inferior oolite group; 624, fuller's earth group; great oolite group; forest marble group; cornbrash. The same formation as it appears North of the Humber and in Sutherland with different characters; 626, range and character of the formation in the Midland Counties; Collyweston and Stonesfield slates.

27 *The middle oolite formation* analogous to the lower oolites in mineral and geographical character; 628, less continuous. The several rocks described: Kelloway rock, Oxford clay, lower calc grit, coralline oolite, Wilts, Oxon. Yorkshire, Weymouth; upper calc grit.

30 *The upper oolite formation;* Kimmeridge clay, composition, layers of ostrea delta; Portland oolite, in Portland, at Chicksgrove, Brill, &c.; the dirt bed of Portland.

631 *The Wealden formation* in three groups; Purbeck beds, Hastings sands, Weald clay.

632 Evidence for the fresh-water origin of the formation.

633 *Foreign localities of the oolitic system* considered; range and extent of the system; its divisions locally the same as in England, but generally there not recognisable; the organic exuviæ unequally distributed.

634 *Disturbances of the oolitic system;* Yorkshire, Dorsetshire, Caithness. On the Continent more extensive.

Page

Organic Remains of the Oolitic System.

The Tables are generally arranged so as to indicate both the relations of British and Foreign species, and the distribution of the fossils in the different formations

635 Plants; 636, polyparia; 637, radiaria; 639, conchifera; 645, gasteropoda.

651 Annulosa, crustacea, insecta, reptilia, pisces, mammalia; 653, summary.

Cretaceous System.

653 *Mineral character* of this and other systems; remarkable surface of chalk country in England; dry valleys of the chalk hills; groups of the chalk system, as exhibited in the South of England, traced to the North, and again specified in Yorkshire; 654, Maestricht and Gosau beds; lower greensand; 655, gault; upper green sand; chalk marl; lower chalk; 656, upper chalk; its layers of flint; pyrites; fissured flints of the Isle of Wight.

656 *Cretaceous system of Ireland;* the basin of Europe; France, Maestricht, North of Germany, Poland, South of Russia, &c.; 657, the Alps, Lombardy.

657 *Convulsions of the cretaceous system* indicated rather by the waste of the chalk, and the accumulation of flint pebbles above, than by direct proof of disturbed rocks *Elie de Beaumont's views; Mr. Lyell's hypothesis.*

Organic Remains of the Cretaceous System.

658 Plants, polyparia; 660, radiaria; 662, conchifera; 666, mollusca.

669 Annulosa; 670, crustacea, cirripeda, pisces, reptilia, and summary.

TERTIARY SYSTEM.

671 *General view* of this system of strata deposited in the sea and lakes; its geological limits toward the older deposits easily known, but toward the modern era difficult to be fixed; reasons for this in the varied nature of the deposits; the uncertainty of the applicability of a common scale of time to the independent changes of organic life on the land and in the sea; general conclusions.

672 *Physical aspect of the globe* at the commencement of the tertiary epoch; various tertiary seas; *tertiary system of England;* lower marine formation, including plastic clay, London clay, and Bagshot sand; 674, fresh-water group of the Isle of Wight; crag, its two mineral types, vast number of shells, &c.

675 *Foreign tertiary system;* under what circumstances deposited, in arms of the sea, included basins, estuaries, lakes; extent and form of the tertiary sea of Europe, &c.; its *relation to existing seas;* 676, comparison of the French and English tertiaries; plastic clay; lower fresh water, upper marine, upper fresh water; Touraine beds; 678, tertiaries in the South of France, on the North of the Alps, at Vienna, in Transylvania, at Gosau, the Untersberg; 679, on the Gosau beds; molasse of Swisserland; subapennine marls; Sicilian deposits.

Relative Antiquity of Tertiary Deposits

680 This important subject is fully discussed; zoological evidence alone admitted to be of general application; *mode of employing this evidence,* in relation to older rocks, stated; proper mode of employing it for tertiary strata exemplified; limits of the reasoning; upper and lower terms for comparison defined; imperfections of the process when applied to particular cases without allowing for local circumstances.

681 *M. Deshayes' investigations* analyzed; marine tertiary species compared to an upper term; (living species;) to a lower term; (basin of Paris;) M. Deshayes' conclusions supported by both tests.

681 *General results.*

682 Organic remains of the marine tertiary strata.

Lacustrine Tertiaries.

684 Data for reasoning concerning their antiquity; certain deposits described; in Central France, in Provence, at Œningen.

685 Lignitic deposits of Swisserland, &c., of *Bovey Tracey,* the Meissner.

686 Organic remains of the lacustrine tertiaries.

688 Dislocations of the tertiary strata in the South of England.

Page

Diluvial Deposits.

688 *Distinctions between these and the tertiary strata;* origin of the term diluvial; relation of the phenomena it includes to the *Noachian Deluge;* proofs of the extraordinary violence of water afforded by these deposits; example of the transport of detritus from the Cumbrian mountains to the South-East, from the Lickey-hill to the East, from the Lincolnshire wolds.

690 Still more extensive effects of analogous causes among and in the vicinity of the Alps; *circumstances* attending the dispersion of the *erratic blocks* of the Alps, and others from Scandinavia, as to arrangement, number, magnitude; direction of the currents to which they owe their transport; general inference on this part of the subject.

691 *Gravel deposits; animal population* at the time of these diluvial currents widely diffused over the Northern regions of the globe; consisted of many species of quadrupeds congenerous with those now living, but for the most part specifically distinct.

692 That they really *lived in those regions* where their remains occur proved by several facts, especially by the history of the ossiferous caves.

Ossiferous caves; their situation, characters, how formed, how filled with bones; Kirkdale cave tenanted by hyænas; 694, Kuhloch tenanted by bears, which died there; Mendip ochre caves and Oreston caves filled by accident and aqueous currents.

695 *Osseous breccia* of the Mediterranean analogous to these latter caves, and filled like them.

The question of the *climate of the Northern regions* in the diluvial or elephantoidal era investigated as a question of Philosophical Zoology; 696, new evidence brought to bear on the subject; the hair-covered fossil animals of the Icy Sea, and the association of *recent shells* with *extinct animals* in Yorkshire. *Other problems* considered; geographical extent of the phenomena; 697, length of the diluvial period; geological monuments of the existence of man; 698, supposed *contemporaneity of human and quadrupedal bones* near Leipzig, Nice, the South of France; the latter example investigated, and a general conclusion adopted on this subject; an attempt to assign the causes of the diluvial phenomena.

699 *Table of Organic Remains in Caverns and Superficial Deposits subsequent to the Tertiary Period.*

Deposits of the Modern Era— Modern Causes in Action.

701 The relation of terraqueous agencies in ancient and modern eras is a proper subject of geological inquiry. On this point the differences of opinion are great, but reducible to three classes, one denying the analogy of ancient and modern physical operations; another admitting agreement in the mode of operation; a third asserting identity of kind and equality of effect; modern causes in action are then examined.

The wasting effects of the atmosphere, chemical, mechanical, or combined, on felspathic and other rocks, contrasted with the conservative power of the ground; waste from humidity, exemplified from changes of heat and moisture, parallel to artificial surfaces of several kinds of stones; 703, influence of frost on slaty rocks; in the Righi mountains.

Effects of rain on druidical monuments, on grit rocks, in limestone cliffs and floors, producing channels like miniature valleys.

704 *Effects of inundations*, in Scotland, in Yorkshire, in the Alps.

Effects of Streams and Rivers.

704 Of two kinds, excavating and transporting; *erosive effects* exemplified in Tynedale, in the Lincolnshire rivers, in various river deltas, in Etna, in Auvergne.

Waterfalls and cataracts, how formed, and continued; at what rate they waste the rocks, and cause recession of the fall; Falls of Niagara.

Transporting action of streams discussed; *rivers without lakes;* waste of the uplands causes elevation and fills irregularities of the lowlands; the Yorkshire Ouse; the valleys near Schaffhausen; in low ground, and at the mouths of rivers, large accessions of sediment happen, new land is formed, and the river mouth is carried forwards or turned in new directions; 706, *the materials* transported vary much, and remind us of the ancient earthy and carbonaceous strata, to which a similar origin has been ascribed; the arrangement of these materials and the general effects of rivers referred to the initial wasting effects of the atmosphere, the power of the river current, and the character of the valley itself.

707 *Rivers with lakes* occasion other peculiarities; the lake receives all the sediment and discharges the water pure; new land is thus formed at the head of the lake; the materials in it being arranged in particular inclined conical surfaces, and measuring the whole transporting effect of the river since it began to flow.

Lacustrine deposits of shelly marl, clay, peat, &c., are analogous to the ancient fresh-water tertiary beds.

708 *Deltas* formed in the sea at the mouths of rivers nearly as in lakes, and coasts extended as on the Adriatic by the same processes; the nature of the materials of which they consist varies according to locality, and both in this respect and in geographical area deltas present close and frequent analogies to some old sedimentary rocks.

Bars at the mouths of rivers, how formed; area of remarkable deltas; geological chronometer formed by them, why defective.

Action of the Sea

709 Erosive and transporting, as in rivers; *wasting* of cliffs, how occasioned; to what degree on the coasts of Yorkshire and Norfolk; extension of marsh land on the same coasts, how produced; different effects of the sea; alternate production and destruction of land; incessant action of the sea in arranging and disturbing the sediment gathered from the land.

709 Coral islands; their growth, quantity of carbonate of lime solidified by them; comparison of coral reefs with certain old limestone strata, how far just, and in what respects delusive.

CHAPTER III.

Description of the Rocks produced by Igneous Agency.

711 *Introduction*, containing a general view of the subjects to be discussed.

PART I.

On Rocks produced by Igneous Operations of a similar Nature to those now taking place.

Section 1.

Description of Volcanic Phenomena in different Parts of the World. General Notion of Volcanic Action.

712 *Phenomena attributed to volcanic action;* phenomena admitted to be volcanic; evidence of volcanic action; local internal commotion; the structure and appearances of the mineral masses on a large scale; the characters of individual rocks; 713, these characters specified; trachyte, greystone; analogy of other volcanic rocks to these.

Division of volcanic products according to their age; the age of valleys assumed as definite, and the volcanic rocks divided by this standard into antediluvial and postdiluvial.

Postdiluvial volcanic rocks, mineral characters of these.

714 *Antediluvial volcanic rocks*, their characters; distinction of subaerial and subaqueous modern volcanos.

Active Volcanos of Europe.

Vesuvius, historical view of its condition; destruction of Pompeii and Stabiæ by dry ashes; of Herculaneum by tufaceous mud; other eruptions noticed.

Phlegrean Fields, subsidence of their volcanic excitation since Vesuvius became active; the phenomena still manifested in the

716 *Solfatara* described; sulphureous vapours; decomposition of the trachytic rocks.

Monte Nuovo, thrown up in the XVIth Century, after earthquakes and flames, consists of loose materials ejected in a few days; heat still manifested at its base.

Grotto del Cane, near Lago Agnano, its mephitic vapours.

Puzzolana, extent of this deposit along the base of the Apennines; its composition, antiquity, elevation above the sea.

Temple of Serapis at Puzzuoli, circumstances which indicate repeated changes of level affecting this locality.

Islands of Procida and Ischia—of varying tufaceous composition; later pumiceous products of Ischia; present high temperature about it.

Page

718 *Other parts of Italy*—Mount Vultur; great antiquity of its action

Rocca Monfina; buried town at Sessa; Ponza Islands; volcanic phenomena of the *Papal States*, Albano, Rome, Viterbo

North of Italy—Volterra; Euganean Hills.

719 *South of Italy*—Lipari Islands, hot springs, volcano; Stromboli, its unintermitting eruptions; beds of puzzolana; dykes.

Sicily—alternate volcanic and neptunian deposits of the tertiary era; Val di Noto; Macaluba; Etna, its vast mass comparatively modern; consists of lava, beds, and tuff, with dykes of trachyte and basalt; erupted in the air, while those of the Val di Noto took place under water.

Sciacca—of recent date, and transient existence; elevated on a line of volcanic action; from deep water.

720 *Grecian Archipelago*—ancient and modern elevations affecting Santorino and the adjacent islands; line of volcanic operations through Milo and Argentiere to the ancient Methone.

Iceland—great scale of its continual volcanic excitement; lines of volcanos; vast lava flood of 1783; island which rose and sunk again in that year; Geysers, their intermitting character explained; solution of silica.

Jan Mayen, supposed to have been in action within a short period.

Extinct Volcanos of Europe.

721 *Portugal*, on the Eastern side of, near Lisbon, in Beira.

Spain—volcanic appearances of Cap di Gaieta; volcanic cones of high antiquity near Olot.

France—North-East of the Pyrenees, Cevennes, Vivarais, Puy, Cantal, Mont Dor; volcanic masses of Auvergne, the Vivarais, Puy en Velay, produced since the date of the valleys, though some are cut by existing streams into ravines; seventy craters in Auvergne; five domitic hills near Clermont distinct in their origin from the other volcanic masses; supposed by Von Buch to have been heaved up, not ejected; characteristic phenomena bearing on this question specified.

723 *Germany*—Eyfel volcanos, cones, craters with lakes; few traces of lava streams; referred to comparatively modern period.

Siebengebirge; basaltic and trachytic hills protruding through schists superposed on tertiary brown coal; basalt of the Westerwald, Vogelsgebirge, Frankfort, Hanau, Cassel; Eisenach; alteration of stratified rocks.

Odenwald, Kaiserstuhl, North of Lake Constance, Rhöngebirge, Fichtelgebirge, Töplitz, Riesengebirge, Erzgeburge; overlying masses of basalt on the western borders of Moravia.

721 *Hungary*—five volcanic groups in the North of Hungary; 1. Schemnitz and Kremnitz; 2. near Gran; 3. mountain of Matra; 4. from Tokai to Eperies; 5. Vihorlet, connected with trachytic mountains of Marmarosch; all of high antiquity in the tertiary period, erupted in a country full of lakes.

Styria—the Gleichenberg trachytic group on the Bosphorus.

Volcanos of Asia.

Asia Minor—the Troad; Smyrna.

Dead Sea—hypothesis proposed concerning the course of the Jordan, and formation of this sea.

Red Sea—active volcano of Zibbel Teir.

725 *Central Asia*—Mount Ararat, Demavend; reports of volcanos in the great depression of the Earth's surface, including the Caspian, &c.; Aral Toobe, Pechan, Tourfan.

Kamtschatka—very active volcanos; volcanic line of the Aleutian Isles to Alaschka; rising of the trachytic island of Unalaschka in 1795; line of volcanic vents by the Kurilean Islands, the Isles of Japan, Loo-Choo, Formosa, the Philippines, Sanguir, Celebes, Ternate, Fidore, the Moluccas, Sambawa, Java, Sumatra, and Barren Island; Eastward range of volcanic phenomena from Sambawa.

Pacific Ocean, volcanic groups and islands of.

Volcanos of Africa.

726 *Madagascar*—Mauritius, Bourbon, its frequent lava streams and ejections; St. Helena, Ascension, Tristan d'Acunha, &c.; Cape Verd Islands.

Canary Islands—Teneriffe, variety of its volcanic products; the Peak; crater eruptions; flank eruptions; other islands the Caldera of Palma; origin of the Barancos; Lancerote.

Madeira—Mount Atlas.

The Azores—St. Michael, El Pico; Island of Sabrina raised and sunk again, 1811.

Volcanos of America.

727 *The Antilles*—nature of these Islands; the volcanic portion classed in two divisions: 1. Grenada, St. Vincent, St. Lucia, Dominica, Montserrat, Nevis, St Christopher, St. Eustachia; 2. Martinique, Guadaloupe, Antigua, St. Barthelemi, St. Martin, St. Thomas; connection of the Caraccas mountains, through the Antilles, with the mountains of Porto Rico, St. Domingo, Jamaica, Cuba.

728 *Continent of America*—*North America*—California; Mexico; great theatre of volcanic action; variety of rocks here produced; East and West line of volcanos extending to the Rivillagigedo Isles; Jorullo, its recent origin, described according to Humboldt; other lines and groups of volcanos in Guatimala, Nicaragua, Columbia; connection of these latter in one system; relation of this line of volcanos to the Andes.

South America—Extension of the line to Chili, where sixteen active volcanos exist; thus all the Western coast of America, South of California, one great theatre of volcanic action.

SECTION 2.

Other Phenomena referable to Volcanic Action.

729 *Review of the* preceding observations on volcanos; other phenomena to be considered.

Earthquakes proved to be connected with volcanic agency, by coincidence or reciprocation of period; instanced by the relation of the eruptions of Etna and Vesuvius to certain earthquakes; other evidence from Columbia, Quito, Chili, Lanzerote, Teneriffe.

730 *Phenomena of earthquakes*; shocks, undulations, vibrations; subterranean noises; eruption of flames; alteration of levels of water; meteorological phenomena; speculations as to other than volcanic causes of earthquakes; electrical accumulation; internal cavities; great extent of the shock of earthquakes no argument against their volcanic origin; not irreconcilable with moderate depth of the exciting cause.

731 *Thermal waters* also connected with volcanic action, because they emit the same gases as volcanos, sulphuretted hydrogen, carbonic acid, nitrogen; this latter given off by Vesuvius, Sciacca; also by hot springs of Castellamare, near Vesuvius, and Auvergne; also by thermal waters of the Alps, Bath, Buxton, Bakewell, Stoney Middleton, and Taate's Well; also in Ceylon and Venezuela; quantity of this gas evolved at Bath.

732 *Situation of thermal waters* shows their relation to volcanic agency; near volcanic groups, elevated chains of mountains, along lines of dislocation, &c.; instances in England.

Heat of such springs related to the period of volcanic excitement, hottest when that is still active, least warm when that has been long extinct; no local chemical action adequate to account for such effects.

733 *Carbonic acid in springs* also indicative of volcanic action; proofs drawn from the position of such springs, in relation to thermal waters, and dislocated strata.

Mud volcanos or salses not really of volcanic origin, but due to local chemical changes, as in Sicily, near Modena, New Andalusia, Trinidad, and Island of Taman; often excited among the substances produced by ancient volcanos; salt springs of Ohio.

Emanations of inflammable gas not admitted as evidence of volcanic action in coal mines, on the Apennines, near Grenoble, in Albania, Baku, where considerable eruptions arise from this cause.

SECTION 3.

Theories of Volcanic Operations considered.

734 *On what data* such theories to be constructed; in one class of theories heat considered as an effect, in another assumed as the general cause; the former limited by rejection of unsatisfactory hypotheses to a certain chemical postulate, *viz.* the oxygenization of metallic bases of the alkalis and earths; the latter reduced to the general theory of internal heat of the Globe; mode of investigation to be followed for the discovery of truth.

Page

735 *Geographical distribution of volcanos;* linear and central volcanic systems, supposed difference of their origin; great volcanic bands.

736 *Proximity* of active volcanos *to the sea* or water, a general fact to which hardly any real exceptions occur; extinct volcanos appear to have had the same relation.

Products of volcanic operations; aeriform fluids evolved; steam, chlorine, sulphuretted hydrogen, sulphurous acid, carbonic acid, nitrogen; circumstances accompanying their appearance.

737 *Substances not gaseous* sublimed; petroleum, sulphuric acid, boracic acid, muriate of ammonia, specular iron ore, muriate of soda, sulphur.

Solidifying substances ejected; lavas, their chemical composition: temperature of flowing; fusibility of basalt; analysis of the lava of Etna; notions concerning the fluidity of lava.

738 *Loose fragments ejected* analogous to lava; general relation of solid volcanic products to trachyte; that rock considered with regard to its origin, from the fusion of granitic rocks; its geological relations strengthen such an opinion.

740 *Constitution of a volcanic* mountain in general; crater of an active volcano; explosion; causes scoriæ; conditions which determine the frequency and force of eruptions.

Craters of eruption; their effects described; quaquaversal dip of the volcanic accumulations round such craters.

741 *Craters of elevation;* that such exist probable from their own appearance, as in Great Canary, in Palma; from the existence of domes of trachyte, as in Auvergne; that such were uplifted, proofs offered; the structure of Puy Chopine examined; other cases of crater formed elevations of rocks not volcanic in the Eyfel, &c; alteration of common limestones to dolomites: supposed sublimation and transfer of magnesia: Crick Hill a case of elevation.

743 The same subject illustrated by testimony of the elevation of volcanic rocks; instances recorded, near Santorino, near Unalaschka, Sciacca, Jorullo; cavities in volcanic mountains; falling in of Papendayang.

744 *Craters of elevation,* how distinguished from those of eruption; to what extent it is supported by distinct evidence; how far admissible; review of this part of the subject.

SECTION 4.

Theory of Volcanic Operations.

745 Recurring to *the two theories* formerly mentioned, their prominent characters are contrasted; the extent to which the theory of internal heat appears to satisfy the conditions of the case specified; the imperfections of this theory stated; products of volcanos examined to test the probability of the theory of oxidation of metallic bases; bearing of the known mean density of the Earth on this discussion.

748 *Statement of the theory* of chemical action; existence of alkaline and earthy metalloids at moderate depths in the Earth; effect of admitting oxygenous substances to them, under the land, under the sea; effect of admitting water to such metallic bodies traced through the various chemical products of volcanos; general conclusion of preference for the chemical theory of volcanos on the ground of its more fully embracing the numerous phenomena observed.

PART II.

Description of Rocks attributed to Volcanic Action taking place under Circumstances different from those before considered.

SECTION 1.

On Trap Rocks.

749 *Introduction.* Connection of the study of modern volcanos with inquiries concerning the effects of the same agencies in ancient geological periods. Composition of basalt; 750, greenstone, syenite, claystone porphyry, pitchstone, &c. &c.; general characters of the foregoing rocks; their mode of occurrence; interposed beds; 751, prismatic structure; spheroidal structure; tabular trap; dykes of trap; their effects on contiguous rocks, on coal.

752 *Origin of trap rocks* derived from igneous agency; some of them quite analogous to the products of existing volcanos; Wernerian hypothesis of the aqueous origin of trap; 753, arguments advanced in its favour shown to be fallacious.

Page

753 *Differences between lava and basalt* explained; accounted for by Dr. Hutton on the principle of pressure modifying the effects of heat; experimentally proved by Sir J. Hall; *why submarine lavas cool slowly.*

755 *Prismatic structure* accounted for; found in recent lava, at Torre del Greco, at Niedermennig, in the Vivarais; greater frequency of dykes in trap rocks than in modern volcanic rocks; such dykes occur in modern volcanos, as in Somma and Vesuvius; reasons why they should more abound in submarine lavas.

756 Trap rocks, *at what periods* formed; cases of the formation of trap among old secondary strata at intervals during their deposition, and at subsequent periods; much of the trap of Ireland and Scotland posterior to the age of the chalk; remarkable prevalence of trap rocks during the tertiary period; abundance of trachyte formed in the same period.

SECTION 2.

Granitic Rocks.

757 *Various conditions of the production of* igneous rocks; distinction of submarine, subterranean, and subaerial volcanic products; granitic and basaltic rocks compared, and thus a general scale of igneous products indicated.

Rocks allied to granite; general argument for the igneous origin of granite; peculiar character of granite; from what circumstances derived.

758 Comparison of *ancient and modern pyrogenous rocks;* felspathic, hornblendo-felspathic, hornblendic; structure of each group; granite veins; view of the *mineral composition of granite;* remarks on its constituent minerals, felspar, quartz, mica; the order of their crystallization; *contemporaneous veins* in granite; *imbedded minerals* in granite; considerations on the *crystallization* of granite; its *elementary composition;* chemical analogies among pyrogenous rocks.

SECTION 3.

Relative Age and characteristic Phenomena of Pyrogenous Rocks.

760 *Age of plutonic rocks,* how to be obtained; by reference to the date of convulsions, formation of veins, interlamination with rocks of known age, division of strata by dykes.

Arran, an example of pyrogenous rocks in general; its general features; its granite upheaved in a melted state, at a certain period, traversed by dykes of other igneous rocks; the general features of these dykes described; 761, alterations of stratified rocks; geographical relations of the pyrogenous rocks; no granite dyke; no hornblendic granite; dependence of dykes and veins on granite elevations.

761 *Granite described;* its ages in Britain various; granite veins abundant; granite without veins rare in Britain; veins in slate of Arran, in limestone, &c. of Glen Tilt, in killas of Cornwall.

762 *Felspar porphyry described* in Ben Nevis, Ben Cruachan, the Cumbrian mountains, North Wales, Cornwall.

763 *Syenite* of Malvern; remarkable position of strata in contact; syenitic dyke.

Hypersthene rock of Cuchullin, Carrock, Radnorshire, Cornwall; that of the Valteline described in its relation to granite; that of Skye in connection with syenite, greenstone, lias, &c.

764 *Gabbro, diallage rock,* serpentine, &c.; localities of these rocks; stratification of serpentine considered.

Greenstone of Salisbury Craig described; its effects on the sandstones and shales included and otherwise placed in contact; subsequent elevation of the rocks.

765 *Basalt* of the *North-East of Ireland* described; section of Fairhead; contact with lias at Portrush; dykes in red conglomerate, in coal measures, in chalk; change of this latter to granular limestone.

766 Basaltic formation of *Upper Teesdale* described; its relation to the carboniferous limestones, shales, and sandstones; remarkable dykes apparently related to the great "Whin Sill;" metallic ores by the side of a dyke.

Melaphyre; opinions of *Von Buch* concerning it; elevation of the Alps; *dolomitization* of limestone; how this latter supposed to be accomplished; probable fate of this hypothesis.

767 *Claystone* of Corygills and Tormore in Arran.

Claystone porphyry of the West coast of Arran.

INDEX.

Page

Amygdaloidal trap of Kinnoul; its mineral composition; effects on sandstones and shales of Oban.

Wacke of the Calton Hill alternates with bituminous shale and argillaceous ironstone.

768 *Pitchstone* in Arran; dykes and interposed beds; mixture with hornstone and greenstone in dykes at Tormore; that of Corygills described.

Trap tuff. Porphyritic breccia, "volcanic sandstone," as seen in Cambria, in Glen Coe, &c., near Edinburgh, near Oban, and in the Caradoc and the Wrekin.

SECTION 4.

Mineral Veins.

769 *State of knowledge* on this subject; want of union between men of science and practical miners; distinction of rocks, dykes, and mineral veins; plan of investigation in the following Treatise.

Substances in a mineral vein; extremely various: in various states of chemical combination; metals, pure, alloyed, mineralized by union with combustibles, with oxygen, with acids; non-metallic substances, the gangue or vein stuff, crystallized, massive, earthy; the "*Rider.*

770 *Mode of aggregation of the substances;* veins filled with one or many sorts of mineral matter; distribution of the different substances various.

General idea of a mineral vein; laminæ of successive crystallization; successive deposition of these laminæ a very plausible hypothesis; less satisfactory on a great scale; the subject further examined; *Werner's opinion* as to the association of certain minerals in veins; occurrence of rolled and fragmented masses in veins; *general form of veins;* rake veins, pipe veins, flat veins, gash veins, strings and feeders of a vein; ridered rock; *metallic substances disseminated* in rocks near veins, in Cornwall, the North of England; tin disseminated in granite; tin floors of Cornwall; stock-works of the Parys mine, Dannemora, Geyer.

771 *Relations of veins to each other;* phenomena at their intersection, as to richness, reciprocity; age of veins as indicated by their intersections; this subject examined; *fundamental postulate;* objections to the admission of this; evidence of Cornish mines on this subject considered; effects in the neighbourhood of a vein; character of veins in different rocks; phenomena of contemporaneous veins: this term limited in its application; conclusion of the argument; intersection of veins resumed; appearances at the crossing; slips and dislocations accompanying veins; real and apparent movement of the mineral masses.

773 *Geographical relations of veins; situations* and character of *veins,* as to height of ground, depth from surface; variation of contents in proportion to depth; *dimensions* of mineral veins, length, width, &c.; *directions* of mineral *veins,* a general law hereon; East and West direction common in Britain and Europe; directions of veins related to their antiquity in Cornwall, in Germany; *direction* of mining *districts.*

774 Connection of veins, fissures, main joints, and cleavage, &c. shown to be real; *relation* of mineral *veins* to the *rocks* which inclose them; importance and difficulty of this subject.

1. Relation to the different kinds of rocks; are veins independent of their chemical and mineral diversity? are certain metals specially associated with particular rocks? instances for and against this notion, in Cornwall, in Silesia, &c., in the North of England; various circumstances of the latter case; quantity of lead in the different "bearing beds" of Alston Moor; general conclusion.

Walls of a vein, altered as if in contact with trap, smoothed and polished; Slickenside, evidence it affords of movement of the masses.

776 2. *Relation to different ages of rocks;* evident as a general fact; metallic veins most abundant in primary and old secondary strata; the same relation obtains in rock dykes; very modern veins at Joachimsthal; contents of veins supposed by Werner to characterise their ages; his descriptions of eight systems of veins.

777 3. *Relation to local centres of igneous action* inquired into; in the older rocks veins most abundant where igneous action has been much developed, and *vice versâ;* in newer rocks the same relation decidedly proved; conclusions adopted on this subject; under what limitations; successive production of trap rocks and mineral veins under the same physical region.

778 *Electricity of veins;* Mr. Fox's experiments considered

Page

CHAPTER IV.

GENERAL INVESTIGATIONS AND INFERENCES.

SECTION 1.

On the Consolidation and Alteration of Stratified Rocks.

778 *Effects of plutonic on stratified rocks;* consolidation, partial fusion, vitrification, crystalline re-arrangement, generation of new minerals; sublimation of particular substances, coal, sulphur, bitumen, &c.; *relation of igneous rocks* to convulsive disturbances of the strata, such that their local exhibition depends on the same cause; comparison of these two orders of effects; existence (simultaneous or successive) of fused rocks below the strata admitted, and their elevations ascribed to mechanical agency.

Consolidation of the strata shown to be in the ratio of their age, or rather of their proximity to the inferior heated regions of the Globe; the lower strata not merely consolidated, but partially altered in structure, composition, arrangement of particles, &c.; gneiss, mica slate, clay slate, considered in this respect; similar review of the secondary and tertiary systems of strata, showing the decreasing effects of heat in them.

Effects of heat on the *deposition* of certain primary strata.

SECTION 2.

On Disturbances of the Strata.

780 1. Geological *periods of convulsion;* proofs of convulsion, founded upon an investigation of the sedimentary deposits, in agitated water, in tranquil water, with or without rivers; sloping deposits rare and peculiar; horizontal deposits of general occurrence; convulsions, how proved directly; how to be inferred from collateral effects, how to determine the *epochs of convulsion,* on the scale of successive deposits; limits of greatest and least antiquity, how to be assigned; question as to the *duration of the convulsions;* were they effected by one or a few vast efforts, or by many small and graduated movements; faults examined with this view; *relation of such faults to axes of convulsion;* inference in favour of short periods of great violence.

783 Table of the geological periods of convulsions in Great Britain; another Table applicable to Europe.

2. *Direction of convulsive movements* governed by certain laws; *Elie de Beaumont's hypothesis* stated; in what manner it can be fairly tested; difficulties in the process; dislocations which are *not* known to be of different ages, and others which *are* known to be of different ages, employed as data for examining the hypothesis; two of M. de Beaumont's systems of convulsion analyzed; more limited inquiry recommended and exemplified.

786 *Direction or strike of the strata* generally parallel to the great chains of mountains, both in the Old and New World; North-East and South-West strike of strata very frequent; parallelism of strikes of strata and curves of magnetic intensity according to M. Necker, in Europe, North America, and Asia.

787 3. Effects of convulsions in altering the *relations of land and water;* elevation of land, at what periods, by what processes effected; general impression on this subject correct, but not complete; *partial elevation of land* a consequence of convulsions, proved by examination of mountain chains and groups, which show angularly elevated strata, and indicate vertical movements; elevation of land above the sea, on what evidence to be admitted.

Ocean level; speculations on this subject; phenomena of this level, within certain limits, examined; by what causes variable; 1. temperature of the water; 2. general change of the dimensions of the Globe, of its internal nucleus; 3. internal movements capable of slightly changing the mean level of the ocean; calculation of the amount upon several assumptions; conclusion adopted, that the mean *oceanic level is nearly permanent.*

Elevation of land not in all cases convulsive, but in some cases *gradual;* extent to which this principle may be applied; *proposal of a hypothesis* on this subject, that the concentric interior masses of the spheroid may not be of uniform density, and that the densities on any one radius may be variable by reason of intestine movements, probable effects of such conditions

ons of land and water, prior to the formathe formation of primary strata; at the the carboniferous epoch; origin of coal; places of growth of the coal plants, before the saliferous epoch; before the oolitic epoch; difficult problem of the relative elevation above the sea of the successive secondary systems of strata.

791 4. Effect of convulsions on the deposition of strata and organic life; *mineral characters* of the several systems of strata compared with the sedimentary deposits now formed by the ordinary processes of Nature; origin of diversity of sediments; no universal strata, *not even* the oldest primary strata, still less the newer rocks; contemporaneity of changes of mineral character and general or local convulsions; dependence of the former on the latter; sudden or gradual effects of this nature; case suited to modern hydrography proposed.

792 *Successive races of marine animals* might be changed by the same operations; transference of organic life; co-ordination of convulsions, changes of organic life and mineral sediments; *fresh-water and marine alternations* dependent on local subterranean movements; difference of cases; proximate and remote convulsions; corresponding effects.

793 *The Weald of Sussex;* Mr. Lyell's hypothesis on its gradual rise and the gradual transfer of its wasted materials to the tertiary basins of London and Hampshire examined; circumstances favourable to it; elevation of the Weald; waste of the deposits there; analogy of the sediments of the two tertiary basins named; resemblance of these to the strata of the Weald; *principal objections to it;* want of correspondence of the succession of beds; deficiency of any rolled masses derived from the Weald.

General View of the State and Progress of Geology.

793 Distinction of Geology from Cosmogony; influence of the Geological Society of London; state of preparation for a geological theory; examination of some leading problems.

Lapse of time; scale of geological chronology, how to be formed; rate of natural processes; augmentation of low lands; shifting of sands; erosion of river channels; difficulties in the reasoning even for comparatively recent terrestrial phenomena; mode of proceeding in the case of older marine periods exemplified. The evidence being,

1. The mechanical deposition of sands, clays, conglomerates, &c.; proof of their formation occupying time; possibility of estimating the proportionate times; assumed unit of time; calculated period of the coal deposits; conglomerates prove that long time elapsed between the deposition of strata locally in contact.

2. Chemical deposits of limestone; difficult to reduce to periods; method proposed of referring them to *equaval* mechanical deposits.

3. Alternation of chemical and sedimentary deposits.

4. Imbedded organic remains; shells of all ages in one only bed; proof of lapse of time; number of shells in a bed not admitted as proof; position of certain plants in sandstones opposed to very great rapidity of deposition.

5. Successions of races of organic beings in the same basin; impressive nature of this evidence; proof of long, but at the same time unknown, periods; inutility of attempting to determine these at present.

6. Successions of convulsions in the same physical region.

7. Alternation of marine and fresh-water products.

8. Alternation of aqueous and igneous products.

9. Metamorphism of rocks.

Successive Conditions of the Globe.

797 Limitation of the inquiry; laws of existing Nature must guide our inquiries; what is possible to be known; sensible *constancy of the dimensions* of the Globe in historical periods; what it proves and allows concerning internal heat and secular refrigeration.

Volcanic action need not be referred exclusively to either of the theories formerly explained.

Displacement of the Earth's axis; why not to be admitted as a geological cause.

Origin of terrestrial organic life; the general analogy of old and modern systems of material beings; special analogies of extinct organic forms to those of particular modern regions.

Alternate periods of convulsion and repose shown to have occurred locally, with definable circumstances of land and sea; application of this principle to large portions of the Globe, by Leibnitz and others; contrary view of Mr. Lyell, uniformity of natural agencies, and continual equality of the sum of their effects in a given time; these opposing views reduced to their postulates, *varying condition* and *unlimited duration;* which of these is true must be found as a result of investigation, not assumed as a basis of argument.

Successive Condition of the Materials of the Globe.

798 *Origin of the elementary substances* no part of Geology, but their changes of condition a proper subject of research; *Wernerian hypothesis* of a chaotic ocean; *Leibnitz's view* of the effects of a globe progressively cooling; *Hutton's hypothesis* of continually renewed phenomena.

Certain sedimentary substances traced through several conditions; tidal sediments, diluvial accumulations, millstone grit; derivation of sedimentary from pyrogenous rocks through one or more steps generally allowed.

Origin of limestone; in modern times from chemical action, from mechanical erosion, from transported exuviæ, from vital phenomena; stratified limestones considered with reference to Dr. Hutton's hypothesis of decaying and renewed continents, and the ultimate reference of all earthy substances to rocks of fusion; Mr. Lyell's view that this derivation of sedimentary from pyrogenous rocks at the surface of the Earth is balanced by reconversion of the former into the latter towards the interior, shown to be not fully in accordance with the hypothesis of uniformity and continual compensation of the effects of internal and external terrestrial agencies.

END OF VOL. VI.

LONDON: PRINTED BY W. CLOWES AND SONS, DUKE STREET, LAMBETH.
